BCSC
Basic and Clinical Science Course™

Published after collaborative review with the European Board of Ophthalmology subcommittee

The American Academy of Ophthalmology is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians.

The American Academy of Ophthalmology designates this enduring material for a maximum of 10 *AMA PRA Category 1 Credits*™. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

CME expiration date: June 1, 2026. *AMA PRA Category 1 Credits*™ may be claimed only once between June 1, 2023, and the expiration date.

To claim *AMA PRA Category 1 Credits*™ upon completion of this activity, learners must demonstrate appropriate knowledge and participation in the activity by taking the posttest for Section 7 and achieving a score of 80% or higher. For further details, please see the instructions for requesting CME credit at the back of the book.

The Academy provides this material for educational purposes only. It is not intended to represent the only or best method or procedure in every case, nor to replace a physician's own judgment or give specific advice for case management. Including all indications, contraindications, side effects, and alternative agents for each drug or treatment is beyond the scope of this material. All information and recommendations should be verified, prior to use, with current information included in the manufacturers' package inserts or other independent sources, and considered in light of the patient's condition and history. Reference to certain drugs, instruments, and other products in this course is made for illustrative purposes only and is not intended to constitute an endorsement of such. Some material may include information on applications that are not considered community standard, that reflect indications not included in approved FDA labeling, or that are approved for use only in restricted research settings. **The FDA has stated that it is the responsibility of the physician to determine the FDA status of each drug or device he or she wishes to use, and to use them with appropriate, informed patient consent in compliance with applicable law.** The Academy specifically disclaims any and all liability for injury or other damages of any kind, from negligence or otherwise, for any and all claims that may arise from the use of any recommendations or other information contained herein.

Ophthalmic researchers and others interested in using artificial intelligence (AI) technologies and Academy-owned materials, including material from the BCSC, should direct permission requests to permissions@aao.org. Without first seeking permission to use these copyrighted materials, individuals and organizations may infringe the Academy's rights. The complete statement on the use of Academy materials and AI is available at aao.org/statement-on-artificial-intelligence.

The Academy acknowledges the *American Society of Ophthalmic Plastic and Reconstructive Surgery (ASOPRS)* for recommending faculty members to the BCSC Section 7 committee.

The Academy also acknowledges the following committees for review of this edition:

Committee on Aging: Jessica R. Chang, MD, Los Angeles, California

Vision Rehabilitation Committee: Linda Lawrence, MD, Salina, Kansas

BCSC Resident/Fellow Reviewers: Sharon L. Jick, MD, *Chair*, St Louis, Missouri; Salma A. Dawoud, MD; Kalla A. Gervasio, MD; Tamara Lee Lenis, MD, PhD; Jonathan E. Lu, MD; Kenneth W. Price, MD; Brittany Simmons, MD

The American Society of Ophthalmic Trauma: Lora R. Dagi Glass, MD, New York, New York

Practicing Ophthalmologists Advisory Committee for Education: Philip R. Rizzuto, MD, *Primary Reviewer,* Providence, Rhode Island; Bradley D. Fouraker, MD, *Chair*, Tampa, Florida; George S. Ellis Jr, MD, New Orleans, Louisiana; Kevin E. Lai, MD, Carmel, Indiana; J. James Rowsey, MD, Largo, Florida; Gaurav K. Shah, MD, San Francisco, California; Scott X. Stevens, MD, Bend, Oregon; Troy M. Tanji, MD, Waipahu, Hawaii

In addition, the Academy acknowledges the following committee for assistance in developing Study Questions and Answers for this BCSC Section:

Resident Self-Assessment Committee: Evan L. Waxman, MD, PhD, *Chair,* Pittsburgh, Pennsylvania; Roxana Fu, MD, Pittsburgh, Pennsylvania

European Board of Ophthalmology: Anna Maino, MBBS, PGCert, *Liaison,* Manchester, England; Francesco Quaranta Leoni, MD, Rome, Italy; Marco Sales Sanz, MD, PhD, Madrid, Spain; Carole A. Jones, MB Bch, Maidstone, England

Recent Past Faculty

Keith D. Carter, MD
Julian D. Perry, MD
Pete Setabutr, MD
Eric A. Steele, MD

Finally, the Academy gratefully acknowledges the contributions of numerous past faculty and advisory committee members who have played an important role in the development of previous editions of the Basic and Clinical Science Course.

Financial Disclosures

Academy staff members who contributed to the development of this product state that within the 24 months prior to their contributions to this CME activity and for the duration of development, they have had no financial interest in or other relationship with any entity whose primary business is producing, marketing, selling, reselling, or distributing health care products used by or in patients.

The authors and reviewers state that within the 24 months prior to their contributions to this CME activity and for the duration of development, they have had the following financial relationships:*

Dr Burkat: Horizon Therapeutics (C)

Dr Chang: Horizon Therapeutics (C)

Dr Fouraker: Addition Technology (C, L), AJL Ophthalmic SA (C, L), Alcon Laboratories (C, L), OASIS Medical (C, L)

Dr Korn: Elsevier (P), Horizon Therapeutics (C), Kaneka Pharma (C), Mallinckrodt Pharmaceuticals (C)

Dr Lai: Twenty Twenty Therapeutics (C)

Dr Lee: Horizon Therapeutics (O)

Dr Quaranta Leoni: Thea (L)

Dr Rowsey: HEO3 (P)

Dr Sales Sanz: Inmunovant (C), Teoxane (L)

Dr Shah: Allergan (C, L, S), DORC International (S), Regeneron Pharmaceuticals (C, L, S)

All relevant financial relationships have been mitigated.

The other authors and reviewers state that within the 24 months prior to their contributions to this CME activity and for the duration of development, they have had no financial interest in or other relationship with any entity whose primary business is producing, marketing, selling, reselling, or distributing health care products used by or in patients.

*C = consultant fee, paid advisory boards, or fees for attending a meeting; E = employed by or received a W-2 from a commercial company; L = lecture fees or honoraria, travel fees or reimbursements when speaking at the invitation of a commercial company; O = equity ownership/stock options in publicly or privately traded firms, excluding mutual funds; P = patents and/or royalties for intellectual property; S = grant support or other financial support to the investigator from all sources, including research support from government agencies, foundations, device manufacturers, and/or pharmaceutical companies

Introduction to the BCSC

The Basic and Clinical Science Course (BCSC) is designed to meet the needs of residents and practitioners for a comprehensive yet concise curriculum of the field of ophthalmology. The BCSC has developed from its original brief outline format, which relied heavily on outside readings, to a more convenient and educationally useful self-contained text. The Academy updates and revises the course annually, with the goals of integrating the basic science and clinical practice of ophthalmology and of keeping ophthalmologists current with new developments in the various subspecialties.

The BCSC incorporates the effort and expertise of more than 100 ophthalmologists, organized into 13 Section faculties, working with Academy editorial staff. In addition, the course continues to benefit from many lasting contributions made by the faculties of previous editions. Members of the Academy Practicing Ophthalmologists Advisory Committee for Education, Committee on Aging, and Vision Rehabilitation Committee review every volume before major revisions, as does a group of select residents and fellows. Members of the European Board of Ophthalmology, organized into Section faculties, also review volumes before major revisions, focusing primarily on differences between American and European ophthalmology practice.

Organization of the Course

The Basic and Clinical Science Course comprises 13 volumes, incorporating fundamental ophthalmic knowledge, subspecialty areas, and special topics:

1 Update on General Medicine
2 Fundamentals and Principles of Ophthalmology
3 Clinical Optics and Vision Rehabilitation
4 Ophthalmic Pathology and Intraocular Tumors
5 Neuro-Ophthalmology
6 Pediatric Ophthalmology and Strabismus
7 Oculofacial Plastic and Orbital Surgery
8 External Disease and Cornea
9 Uveitis and Ocular Inflammation
10 Glaucoma
11 Lens and Cataract
12 Retina and Vitreous
13 Refractive Surgery

References

Readers who wish to explore specific topics in greater detail may consult the references cited within each chapter and listed in the Additional Materials and Resources section at the back of the book. These references are intended to be selective rather than exhaustive,

chosen by the BCSC faculty as being important, current, and readily available to residents and practitioners.

Multimedia

This edition of Section 7, *Oculofacial Plastic and Orbital Surgery,* includes videos related to topics covered in the book and interactive content, or "activities," developed by members of the BCSC faculty. The videos and activities are available to readers of the print and electronic versions of Section 7 (www.aao.org/bcscvideo_section07 and www.aao.org/bcscactivity_section07). Mobile-device users can scan the QR codes below (a QR-code reader may need to be installed on the device) to access the videos and activities.

Videos

Activities

Self-Assessment and CME Credit

Each volume of the BCSC is designed as an independent study activity for ophthalmology residents and practitioners. The learning objectives for this volume are given on page 1. The text, illustrations, and references provide the information necessary to achieve the objectives; the study questions allow readers to test their understanding of the material and their mastery of the objectives. Physicians who wish to claim CME credit for this educational activity may do so by following the instructions given at the end of the book.*

Conclusion

The Basic and Clinical Science Course has expanded greatly over the years, with the addition of much new text, numerous illustrations, and video content. Recent editions have sought to place greater emphasis on clinical applicability while maintaining a solid foundation in basic science. As with any educational program, it reflects the experience of its authors. As its faculties change and medicine progresses, new viewpoints emerge on controversial subjects and techniques. Not all alternate approaches can be included in this series; as with any educational endeavor, the learner should seek additional sources, including Academy Preferred Practice Pattern Guidelines.

The BCSC faculty and staff continually strive to improve the educational usefulness of the course; you, the reader, can contribute to this ongoing process. If you have any suggestions or questions about the series, please do not hesitate to contact the faculty or the editors.

The authors, editors, and reviewers hope that your study of the BCSC will be of lasting value and that each Section will serve as a practical resource for quality patient care.

* There is no formal American Board of Ophthalmology (ABO) approval process for self-assessment activities. Any CME activity that qualifies for ABO Continuing Certification credit may also be counted as "self-assessment" as long as it provides a mechanism for individual learners to review their own performance, knowledge base, or skill set in a defined area of practice. For instance, grand rounds, medical conferences, or journal activities for CME credit that involve a form of individualized self-assessment may count as a self-assessment activity.

Introduction to Section 7

For over 50 years, BCSC has been the essential reference for ophthalmologists seeking to acquire or maintain expertise in the field's subspecialties. What is now known as Section 7, *Oculofacial Plastic and Orbital Surgery,* provides comprehensive coverage, an emphasis on anatomy, and numerous visual aids that make it an ideal resource for both established practitioners and trainees alike. In this major revision of *Oculofacial Plastic and Orbital Surgery*, the Section 7 BCSC committee, composed of leading experts, has worked tirelessly to include the most up-to-date information and techniques.

One of the most significant contributions of this book is its strong focus on anatomy; its meticulously detailed diagrams of cadaveric dissections aid in clinical and surgical learning. The inclusion of these visual aids provides readers with an immersive and highly informative experience, allowing them to grasp complex concepts and procedures with greater ease and clarity. Other illustrations and photographs—this edition features over 170 new images—provide an excellent supplement to the text, giving readers a deeper understanding of the procedures discussed. Eleven new surgical videos and 2 new activities serve to further engage the reader and provide a more comprehensive learning experience.

It is important to note that while this book serves as an excellent foundation, it is not intended to be the sole source of learning for practitioners. Rather, readers should use it in conjunction with other sources listed in each chapter's reference sections and those that appear in Additional Materials and Resources to stay current with the latest developments in the field.

Objectives

Upon completion of BCSC Section 7, *Oculofacial Plastic and Orbital Surgery*, the reader should be able to

- describe the normal anatomy and function of orbital and oculofacial tissues
- identify general and specific pathophysiologic processes (including congenital, infectious, inflammatory, traumatic, neoplastic, and involutional processes) that affect the structure and function of these tissues
- select appropriate examination techniques and protocols for diagnosing disorders of the oculofacial and orbital systems
- select from among the various imaging and ancillary studies available those that are most useful for a given patient
- describe appropriate differential diagnoses for disorders of the oculofacial and orbital tissues
- list the indications, advantages, and disadvantages for enucleation, evisceration, and exenteration
- describe functional and cosmetic indications in the medical and surgical management of oculofacial conditions
- state the principles of medical and surgical management of conditions affecting the oculofacial and orbital system
- describe the management of orbital compartment syndrome
- identify the major postoperative complications of oculofacial plastic and orbital surgery
- describe how the lacrimal pump mechanism drains the tear lake

PART I
Orbit

CHAPTER 1

Orbital Anatomy

This chapter includes related activities. Go to www.aao.org/bcscactivity_section07 or scan the QR codes in the text to access this content.

Highlights

- The orbit is composed of 7 bones that create a quadrilateral pyramid, which condenses to 3 walls at the orbital apex.
- The optic canal and superior and inferior orbital fissures transmit the critical neurovascular structures of the orbit and can be anatomically subdivided by the annulus of Zinn.
- The vasculature of the orbit arises from the ophthalmic artery by way of the internal carotid artery. Branches of the ophthalmic artery subsequently form anastomoses with branches of the external carotid in the eyelid and periorbital region.
- The 4 paranasal sinuses are immediately adjacent to the orbit; they are rudimentary or very small at birth, developing and enlarging during childhood and adolescence.
- Pathologic processes in the paranasal sinuses can contribute to diseases of the orbit.

BCSC Section 2, *Fundamentals and Principles of Ophthalmology,* also discusses ocular anatomy and includes many illustrations.

Dimensions

The orbits are bony cavities that contain the globes, extraocular muscles, nerves, fat, and blood vessels. Each bony orbit is pear shaped, tapering posteriorly toward the apex and the optic canal. The medial orbital walls are approximately parallel and are separated by 2.5 cm, on average, in an adult. The widest dimension of the orbit is approximately 1 cm behind the anterior orbital rim. Average measurements of the adult orbit are shown in Table 1-1 and Figure 1-1.

Topographic Relationships

The orbital walls are composed of 7 bones: ethmoid, frontal, lacrimal, maxillary, palatine, sphenoid, and zygomatic. The composition of each of the 4 walls and their locations in relation to adjacent extraorbital structures are shown in Figures 1-2, 1-3, and 1-4 and summarized in the following sections. A video available at https://anatomyzone.com/head/orbit/orbit-bones-eye/ demonstrates the relationship of the orbital bones to each other.

Table 1-1 Average Dimensions of the Adult Orbit

Volume	30 cm^3
Entrance height	3.5 cm
Entrance width	4.0 cm
Medial wall length	4.5–5.0 cm
Lateral wall length	4.0 cm
Distance from posterior globe to optic foramen	1.8 cm
Length of orbital segment of optic nerve	2.5–3.0 cm
Length of intracanalicular segment of optic nerve	0.4–1.0 cm
Length of intracranial segment of optic nerve	0.3–1 cm; usually ≈1 cm

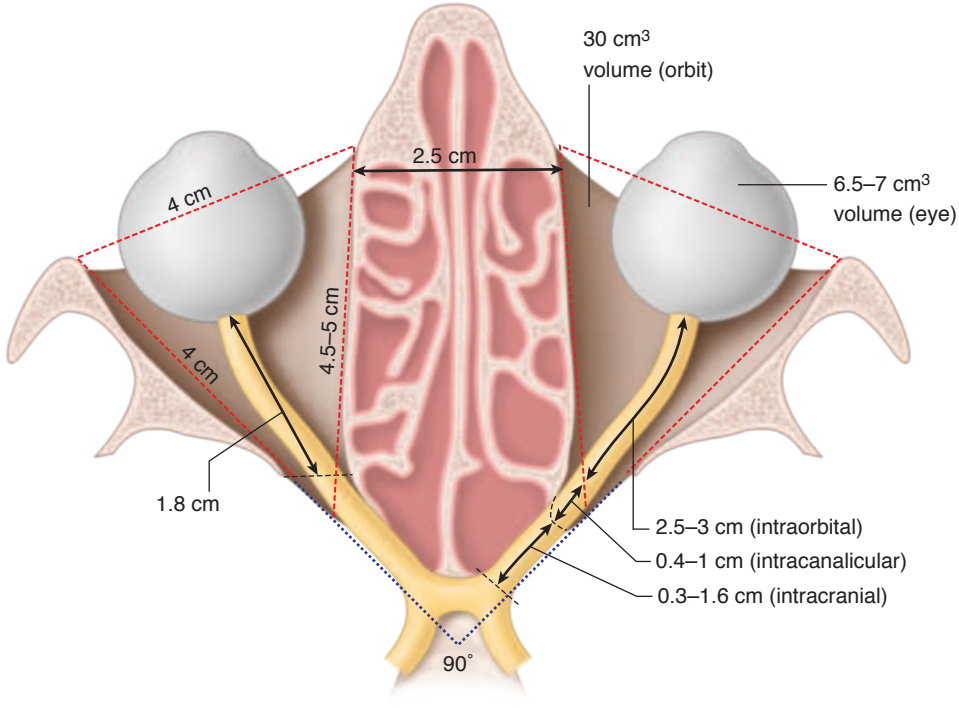

Figure 1-1 Average orbital dimensions and volume. *(Illustration by Mark Miller, based on an image in Watanabe K, ed.* Anatomy for Plastic Surgery of the Face, Head, and Neck. *1st ed. Thieme; 2016.)*

Roof of the Orbit

The roof of the orbit is composed of the orbital plate of the frontal bone and the lesser wing of the sphenoid bone (Fig 1-2A). It is located adjacent to the anterior cranial fossa and frontal sinus and includes the following important landmarks:

- the *fossa of the lacrimal gland,* which contains the orbital lobe of the lacrimal gland
- the *fossa for the trochlea of the superior oblique tendon,* located 5 mm behind the superonasal orbital rim
- the *supraorbital notch,* or *foramen,* which transmits the supraorbital vessels and the supraorbital branch of the frontal nerve
- the *supratrochlear notch*, or *foramen*, which transmits the supratrochlear vessels and the supratrochlear branch of the frontal nerve

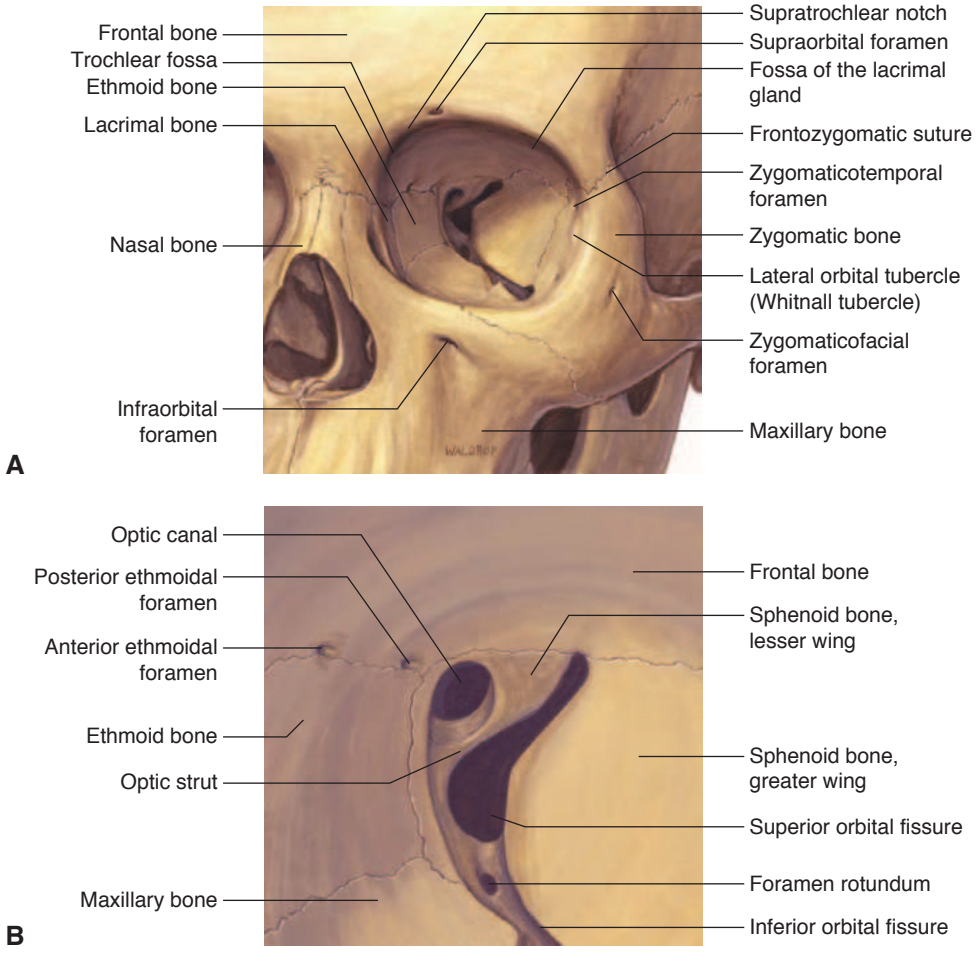

Figure 1-2 Orbital bones. **A,** Frontal view, left side. **B,** Apex, left side. *(Reproduced with permission from Dutton JJ.* Atlas of Clinical and Surgical Orbital Anatomy. *Saunders; 1994:8.)*

Lateral Wall of the Orbit

The lateral wall of the orbit is the thickest and strongest of the orbital walls. It is composed of the zygomatic bone and the greater wing of the sphenoid bone and is separated from the lesser wing (portion of the orbital roof) by the superior orbital fissure (Fig 1-3A). It is located adjacent to the middle cranial fossa and the temporal fossa and commonly extends anteriorly to the equator of the globe, helping to protect the posterior half of the eye while maximizing peripheral vision. Important landmarks include the following:

- the *lateral orbital tubercle* (*Whitnall tubercle*; see Figs 1-2A, 1-3A), with multiple attachments, including the lateral canthal tendon, the lateral horn of the levator aponeurosis, the check ligament of the lateral rectus, and the suspensory ligament of the globe (Lockwood ligament)
- the *frontozygomatic suture* (see Figs 1-2A, 1-3A), located 1 cm above the lateral orbital tubercle

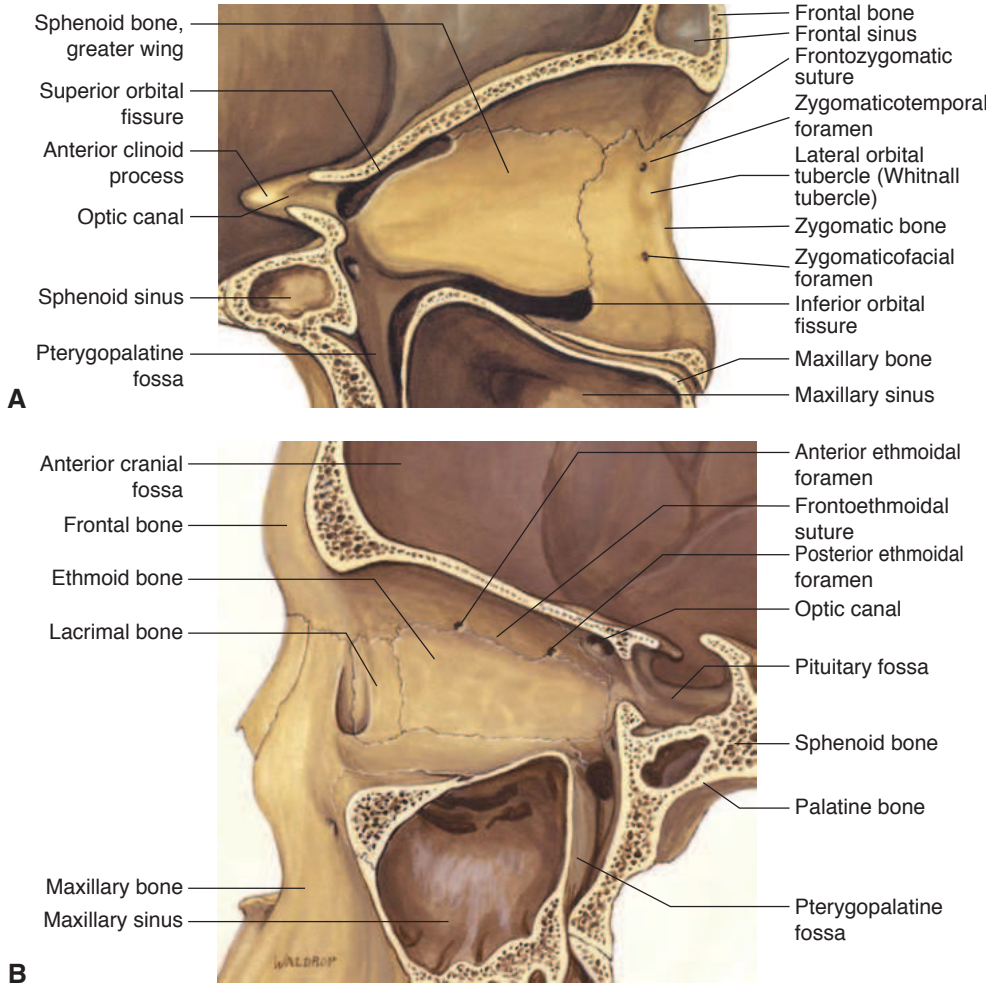

Figure 1-3 Orbital bones, internal views. **A,** Lateral wall, left side. **B,** Medial wall, left side. *(Modified with permission from Dutton JJ.* Atlas of Clinical and Surgical Orbital Anatomy. *Saunders; 1994:9–10.)*

Medial Wall of the Orbit

The medial wall of the orbit is composed of the orbital plate of the ethmoid bone, the lacrimal bone, the frontal process of the maxillary bone, and the lesser wing of the sphenoid bone (Fig 1-3B). Of these, only the lacrimal bone is wholly within the orbital confines. The medial wall of the orbit is located adjacent to the ethmoid and sphenoid sinuses and nasal cavity. The medial wall of the optic canal is formed by the lesser wing of the sphenoid, which is also the lateral wall of the sphenoid sinus (see Fig 1-2B).

The *frontoethmoidal suture* is an important landmark and marks the approximate level of the cribriform plate, the roof of the ethmoid sinuses, the floor of the anterior cranial fossa, and the foramina of the anterior and posterior ethmoidal arteries (Fig 1-3B).

The thinnest walls of the orbit are the *ethmoid bone* (lamina papyracea), between the orbit and the ethmoid sinuses along the medial wall, and the *maxillary bone,* particularly in its posteromedial portion. These are the bones most frequently fractured because of indirect orbital ("blowout") fractures (see Chapter 6). Acute bacterial infections of the ethmoid sinuses may extend through the ethmoid bone or neurovascular perforations to form a subperiosteal abscess and extend into the orbital soft tissues.

Floor of the Orbit

The orbital floor is made up of the orbital plates of the maxillary, palatine, and zygomatic bones (Fig 1-4). The floor of the orbit forms the roof of the maxillary sinus. It does not extend to the orbital apex but instead ends at the inferior orbital fissure; hence, it is the shortest of the orbital walls.

Important landmarks include the *infraorbital groove* and *infraorbital canal,* which transmit the infraorbital artery and vein and the maxillary division of the trigeminal nerve (Fig 1-5).

Dutton JJ. *Atlas of Clinical and Surgical Orbital Anatomy.* 2nd ed. Saunders; 2011.

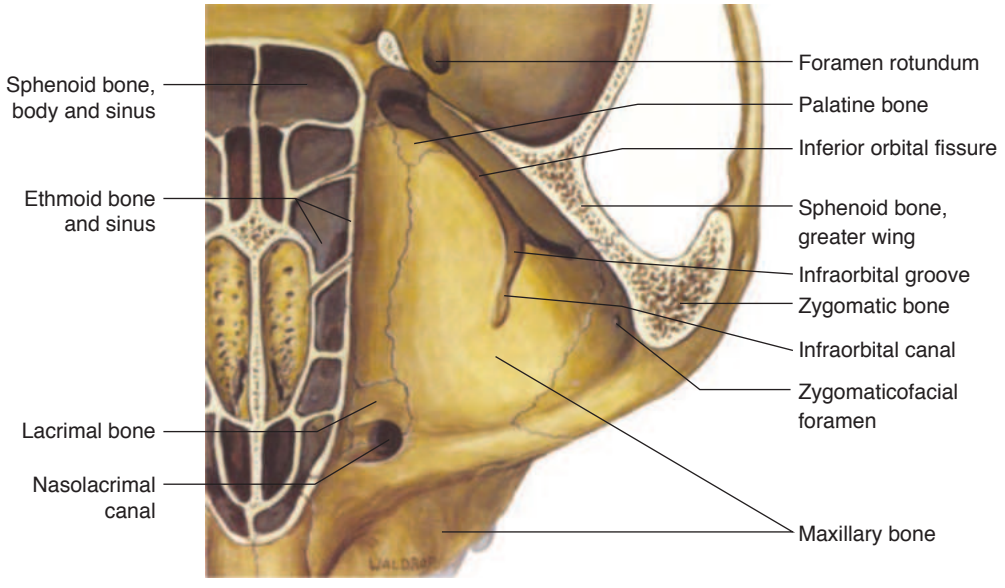

Figure 1-4 Orbital bones, orbital floor, internal view, left side. *(Modified with permission from Dutton JJ.* Atlas of Clinical and Surgical Orbital Anatomy. *Saunders; 1994:11.)*

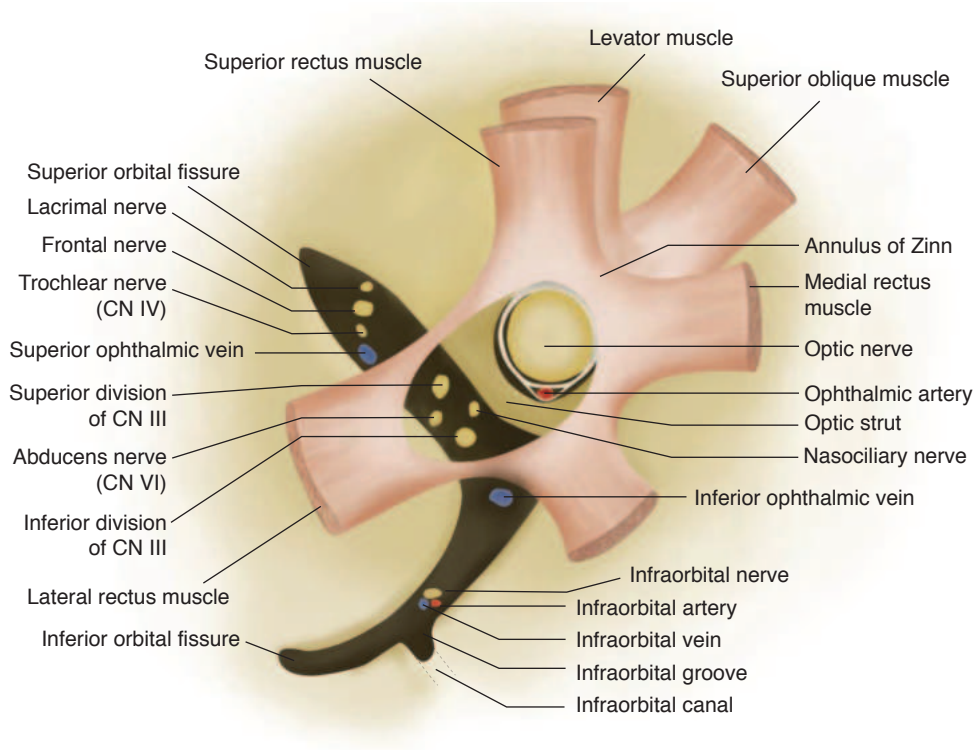

Figure 1-5 View of orbital apex, right orbit. The ophthalmic artery enters the orbit through the optic canal, whereas the superior and inferior divisions of the oculomotor nerve (cranial nerve [CN] III), abducens nerve (CN VI), and the nasociliary nerve enter the muscle cone through the oculomotor foramen. The trochlear nerve (CN IV), the frontal and lacrimal nerves, and the ophthalmic vein enter through the superior orbital fissure and thus lie within the periorbita but outside the muscle cone. Note that the presence of many nerves and arteries along the lateral side of the optic nerve mandates a superonasal surgical approach to the optic nerve in the orbital apex. *(Illustration by Cyndie C. H. Wooley.)*

Apertures

The orbital walls are perforated by several important apertures (Table 1-2; see also Figs 1-2 through 1-5).

Ethmoidal Foramina

The anterior and posterior ethmoidal arteries pass through the corresponding ethmoidal foramina in the medial orbital wall, along the frontoethmoidal suture (see Fig 1-3B). These foramina provide a potential route of entry into the orbit for pathogens and neoplasms from the ethmoid sinuses, and they also serve as a surgical landmark for the superior extent of medial wall surgery. Limiting manipulation of the medial orbital wall to the area below the level of the foramina helps prevent inadvertent entry into the cranial vault.

Table 1-2 Orbital Apex Apertures

Superior Orbital Fissure
Outside the annulus of Zinn • Lacrimal nerve (CN V_1) • Frontal nerve (CN V_1) • Trochlear nerve (CN IV) • Superior ophthalmic vein
Inside the annulus of Zinn • Superior division of oculomotor nerve (CN III) • Inferior division of oculomotor nerve (CN III) • Abducens nerve (CN VI) • Nasociliary nerve (CN V_1)
Inferior Orbital Fissure
• Infraorbital nerve (CN V_2) • Infraorbital artery • Infraorbital vein
Optic Canal
• Optic nerve (CN II) • Ophthalmic artery • Sympathetic nerves

Superior Orbital Fissure

The superior orbital fissure separates the greater and lesser wings of the sphenoid bone and transmits cranial nerves (CNs) III, IV, and VI; the first *(ophthalmic)* division of CN V; and parasympathetic nerve fibers (see Figs 1-2B and 1-5). Most of the venous drainage from the orbit passes through this fissure via the superior ophthalmic vein to the cavernous sinus.

Inferior Orbital Fissure

The inferior orbital fissure is bounded by the sphenoid, maxillary, and palatine bones and lies between the lateral orbital wall and the orbital floor (see Figs 1-2, 1-4, 1-5). It transmits the second *(maxillary)* division of CN V, including the zygomatic nerve, and branches of the inferior ophthalmic vein leading to the pterygoid plexus. The maxillary nerve (V_2) exits the skull through the foramen rotundum and travels through the pterygopalatine fossa to enter the orbit at the inferior orbital fissure. After giving off the zygomatic branch, the nerve becomes the infraorbital nerve and travels anteriorly in the floor of the orbit through the infraorbital canal, emerging on the face of the maxillary bone 1 cm below the inferior orbital rim. The infraorbital nerve carries sensation from the lower eyelid, cheek, upper lip, upper teeth, and gingiva.

Zygomaticofacial and Zygomaticotemporal Foramina

The zygomaticofacial foramen and zygomaticotemporal foramen transmit vessels and branches of the zygomatic nerve through the lateral orbital wall to the cheek and the temporal fossa, respectively (see Figs 1-2A, 1-3A).

Nasolacrimal Canal

The nasolacrimal canal extends from the lacrimal sac fossa to the inferior meatus beneath the inferior turbinate in the nose. This canal transmits the nasolacrimal duct, which is continuous from the lacrimal sac to the nasal mucosa (see Chapter 14, Fig 14-2).

Optic Canal

The optic canal is 8–10 mm long and is located within the lesser wing of the sphenoid bone. This canal is separated from the superior orbital fissure by the bony optic strut (see Fig 1-2B). The optic nerve, ophthalmic artery, and sympathetic nerves pass through this canal. The orbital end of the canal is the *optic foramen*, which normally measures less than 6.5 mm in diameter in adults. Optic canal enlargement accompanies the expansion of the nerve, as seen with optic nerve gliomas. Narrowing of the canal occurs in disorders such as fibrous dysplasia. Blunt trauma may cause an optic canal fracture or shearing of the pial vessels within the canal, resulting in optic neuropathy.

Soft Tissues

Periorbita

The periorbita is the periosteal lining of the orbital bones. At the orbital apex, it fuses with the dura mater covering the optic nerve. Anteriorly, the periorbita is continuous with the orbital septum and the periosteum of the facial bones. The orbital septum arises anteriorly from the orbital rim. The line of fusion of these layers at the orbital rim is called the *arcus marginalis*. The periorbita adheres loosely to the bone except at the orbital margin, sutures, fissures, foramina, tubercles, and canals. In an exenteration, the periorbita can be easily separated except at these firm attachments. Subperiosteal fluid, such as pus or blood, is typically restricted within these boundaries. The periorbita is richly innervated by sensory nerves.

Intraorbital Optic Nerve

The intraorbital segment of the optic nerve has an S-shaped curve and is about 3 cm long, which allows the eye to rotate and move forward with some freedom, without placing excessive tension on the posterior globe insertion (see Fig 1-1). The optic nerve is 4 mm in diameter and is surrounded by the internal sheath, the arachnoid sheath, and the dural sheath, which are continuous with the pia mater, arachnoid mater, and dura mater that envelop the brain. The dura mater covering the posterior portion of the intraorbital optic nerve fuses with the annulus of Zinn at the orbital apex and is continuous with the periosteum of the optic canal.

Extraocular Muscles and Orbital Fat

The extraocular muscles are responsible for the movement of the eye and for synchronous movements of the eyelids (see BCSC Section 2, *Fundamentals and Principles of Ophthalmology*). All extraocular muscles, except the inferior oblique muscle, originate at the orbital apex

and travel anteriorly to insert onto the eye or eyelid. The 4 *rectus muscles* (superior, medial, lateral, and inferior) originate at the annulus of Zinn (see Fig 1-5). The *levator palpebrae superioris muscle* arises above the annulus on the lesser wing of the sphenoid bone. The *superior oblique muscle* originates slightly medial to the levator muscle origin and travels anteriorly through the trochlea on the superomedial orbital rim, where it turns posterolaterally and inserts on the globe beneath the superior rectus muscle. The *inferior oblique muscle* originates in the anterior orbital floor lateral to the lacrimal sac and travels posterolaterally within the lower eyelid retractors to insert inferolateral to the macula. A video available at https://anatomyzone.com/head/eye/extraocular-muscles/ demonstrates the functions of the extraocular muscles.

In the anterior portion of the orbit, the rectus muscles are connected by a membrane known as the *intermuscular septum*. When viewed in the coronal plane, this membrane forms a ring that divides the orbital fat into the *intraconal fat (intraconal surgical space)* and the *extraconal fat (extraconal surgical space)* (see Chapter 7, Fig 7-1). These anatomic designations are helpful for describing the location of a mass on magnetic resonance imaging (MRI) or a computed tomography (CT) scan (see Chapter 2). Knowledge of these spaces helps direct the surgical approach to the mass.

The orbit is further divided by many fine fibrous septa that unite and support the globe, optic nerve, and extraocular muscles (Fig 1-6). Orbital trauma can disrupt this supporting system and contribute to globe displacement and restriction. In some cases of diplopia after a fracture, restriction of eye movement is caused not by entrapment of muscle itself but rather by entrapment of orbital connective tissues.

The motor innervation of the extraocular muscles arises from cranial nerves III, IV, and VI. The superior rectus and levator muscles are supplied by the superior division of CN III *(oculomotor nerve)*. The inferior rectus, medial rectus, and inferior oblique muscles are supplied by the inferior division of CN III. The lateral rectus is supplied by CN VI *(abducens nerve)*. The cranial nerves to the rectus muscles enter the orbit posteriorly through the superior orbital fissure and travel through the intraconal fat to enter the intraconal surface of the muscles at the junction of the posterior third and anterior two-thirds. CN IV *(trochlear nerve)* crosses over the levator muscle and innervates the superior oblique

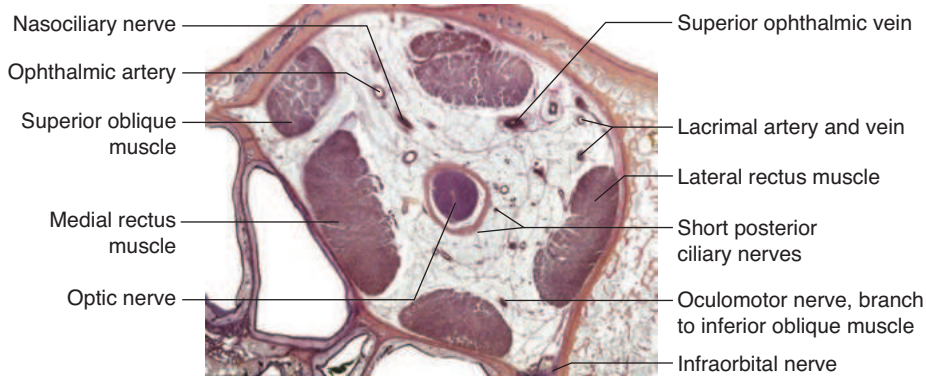

Figure 1-6 Cross-section of the left orbit at mid-orbit and at the widest extent of the extraocular muscles. Note the pink-stained fibrous tissue septa in the intraconal space.

on the superior or medial surface at its posterior third. The motor fibers from the inferior division of CN III to the inferior oblique muscle travel anteriorly on the lateral aspect of the inferior rectus to enter the muscle on its posterior surface.

Annulus of Zinn

The annulus of Zinn is the fibrous ring formed by the common origin of the 4 rectus muscles (see Fig 1-5). The ring encircles the optic foramen and the central portion of the superior orbital fissure. The superior origin of the lateral rectus muscle separates the superior orbital fissure into 2 compartments (see Table 1-2). The portion of the orbital apex enclosed by the annulus is called the *oculomotor foramen.* This opening transmits CN III (upper and lower divisions), CN VI, and the nasociliary branch of the ophthalmic division of CN V *(trigeminal nerve).* The superior and lateral aspect of the superior orbital fissure external to the muscle cone transmits CN IV as well as the frontal and lacrimal branches of the ophthalmic division of CN V. Cranial nerve IV is the only nerve that innervates an extraocular muscle and does not pass directly into the muscle cone when entering the orbit. A retrobulbar block therefore spares this muscle's action. Cranial nerves III and VI pass directly into the muscle cone through the oculomotor foramen. The superior ophthalmic vein passes through the superolateral portion of the superior orbital fissure outside the oculomotor foramen.

Vasculature of the Orbit

The blood supply to the orbit arises primarily from the *ophthalmic artery* (Figs 1-7 to 1-9; Activities 1-1, 1-2), which is a branch of the internal carotid artery. Smaller contributions come from the external carotid artery by way of the internal maxillary and facial arteries. The ophthalmic artery travels underneath the intracranial optic nerve through the dura mater along the optic canal to enter the orbit. The major branches of the ophthalmic artery are the

- branches to the extraocular muscles
- central retinal artery (to the optic nerve and retina)
- posterior ciliary arteries (long to the anterior segment and short to the choroid)

Terminal branches of the ophthalmic artery travel anteriorly and form rich anastomoses with branches of the external carotid in the face and periorbital region (see Fig 1-9). A video available at https://anatomyzone.com/head/eye/eyeball-blood-supply/ demonstrates blood supply to the eyes.

The *superior ophthalmic vein* provides the main venous drainage of the orbit (see Figs 1-7, 1-8). This vein originates in the superonasal quadrant of the orbit and extends posteriorly through the superior orbital fissure into the cavernous sinus. Frequently, the

superior ophthalmic vein appears on axial orbital CT scans as the only structure coursing diagonally through the superior orbit. Many anastomoses occur anteriorly with the veins of the face as well as posteriorly with the pterygoid plexus.

Nerves

Sensory innervation to the periorbital area is provided by the ophthalmic and maxillary divisions of CN V (Fig 1-10). After branching off at the trigeminal ganglion, the ophthalmic division of CN V travels in the lateral wall of the cavernous sinus, dividing into 3 main branches: frontal, lacrimal, and nasociliary. The *frontal nerve* and *lacrimal nerve* enter the orbit through the superior orbital fissure outside the annulus of Zinn (see Fig 1-5) and

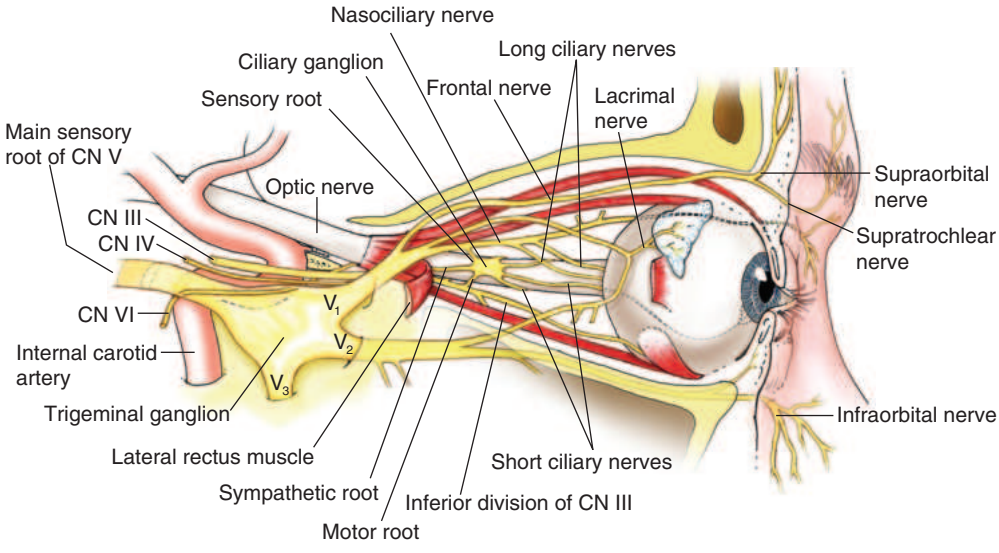

Figure 1-10 Sensory innervation of the right orbit and periorbital area. The sensory root of the trigeminal nerve (CN V) synapses in the trigeminal ganglion just lateral to the cavernous sinus. Three divisions of the trigeminal nerve arise from the ganglion: the ophthalmic branch (V_1); maxillary branch (V_2); and mandibular branch (V_3). The ophthalmic branch (V_1) gives rise to the frontal nerve, which branches into the supraorbital and supratrochlear nerves. The ophthalmic branch (V_1) also gives rise to the lacrimal nerve and nasociliary nerve; the nasociliary nerve then provides the short and long ciliary nerves to the globe. The maxillary branch (V_2) produces the infraorbital, zygomaticotemporal (not pictured), and zygomaticofacial (not pictured) nerves. Sympathetic root carrying postganglionic sympathetic fibers from the superior cervical ganglion and carotid plexus and motor root carrying preganglionic parasympathetic fibers from the inferior division of the oculomotor nerve are also depicted. *(Illustration by Dave Peace.)*

travel anteriorly in the extraconal fat to innervate the medial canthus *(supratrochlear branch),* upper eyelid *(lacrimal* and *supratrochlear branches),* and forehead (*supraorbital* and *supratrochlear branches*). The *nasociliary branch* enters the orbit through the superior orbital fissure within the annulus of Zinn, entering the intraconal space and traveling anteriorly to innervate the eye via the ciliary branches. The short ciliary nerves penetrate the sclera after passing through the ciliary ganglion without synapse. The long ciliary nerves pass by the ciliary ganglion and enter the sclera, where they extend anteriorly to supply the iris, cornea, and ciliary muscle.

The muscles of facial expression, including the orbicularis oculi, procerus, corrugator supercilii, and frontalis muscles, receive their motor supply by way of branches of CN VII (the facial nerve) (see Chapter 9, Figs 9-4 to 9-6). The facial nerve exits the skull through the stylomastoid foramen just anterior to the outer ear. The motor root continues anteriorly into the parotid gland, where it divides into 5 branches *(temporal, zygomatic, buccal, marginal, and cervical)* that course to the muscles of facial expression and enter each muscle on its posterior surface.

Parasympathetic innervation, which controls accommodation, pupillary constriction, and lacrimal gland stimulation, follows a complicated course. Parasympathetic innervation enters the eye as the short posterior ciliary nerves after synapsing within the ciliary

ganglion. Parasympathetic innervation to the lacrimal gland originates in the lacrimal nucleus of the pons and eventually joins the lacrimal nerve to enter the lacrimal gland.

Sympathetic activity originates in the hypothalamus, with sympathetic fibers descending through the brainstem to the spinal cord, where they continue. Fibers destined for the orbit synapse in the ciliospinal center of Budge-Waller and then travel with branches of the carotid artery to enter the orbit. The sympathetic nerves carry innervation for pupillary dilation, vasoconstriction, smooth muscle function of the eyelids and orbit, and hidrosis. The nerve fibers follow the arterial supply to the pupil, eyelids, and orbit and travel anteriorly in association with the long ciliary nerves. Interruption of this innervation results in the familiar signs of Horner syndrome: ptosis of the upper eyelid, elevation of the lower eyelid, miosis, anhidrosis, and vasodilation. (See BCSC Section 5, *Neuro-Ophthalmology,* for detailed discussion of neuro-ophthalmic anatomy.)

Lacrimal Gland

The lacrimal gland is composed of a larger *orbital lobe* and a smaller *palpebral lobe* (see BCSC Section 2, *Fundamentals and Principles of Ophthalmology*). The gland is located within a fossa of the frontal bone in the superotemporal orbit. Ducts from both lobes pass through the palpebral lobe and empty into the upper conjunctival fornix. Frequently, a portion of the palpebral lobe is visible on slit-lamp examination with the upper eyelid everted. Biopsy is generally not performed on the palpebral lobe or temporal conjunctival fornix because it can interfere with lacrimal secretion. The orbital lobe of the lacrimal gland may prolapse inferiorly out of the fossa and present as a mass in the lateral upper eyelid.

Periorbital Structures

Nose and Paranasal Sinuses

The paranasal sinuses are rudimentary at birth and increase in size through adolescence. They lie adjacent to the floor, medial wall, and anterior portion of the orbital roof and drain into the nasal cavity (Fig 1-11). The sinuses decrease the weight of the skull and function as resonators for the voice. They also support the nasal passages by filtering, warming, and humidifying inhaled air. Pathologic processes in these spaces may secondarily affect the orbit and include sinonasal carcinomas, inverted papillomas, invasive fungal sinusitis, granulomatosis with polyangiitis, mucoceles, and sinusitis resulting in orbital cellulitis and/or abscess.

The nasal cavity is divided into 2 nasal fossae by the nasal septum. The lateral wall of the nose has 3 bony projections: the superior, middle, and inferior conchae *(turbinates).* The turbinates are covered by nasal mucosa and overhang the corresponding meati. Just cephalad to the superior concha is the *sphenoethmoidal recess.* The nasolacrimal duct opens into the inferior meatus. The nasal cavity is lined by a pseudostratified, ciliated columnar epithelium and goblet cells. The mucous membrane overlying the lateral alar cartilage is hair bearing and, therefore, less suitable for use as a composite graft in eyelid reconstruction than the mucoperichondrium over the nasal septum.

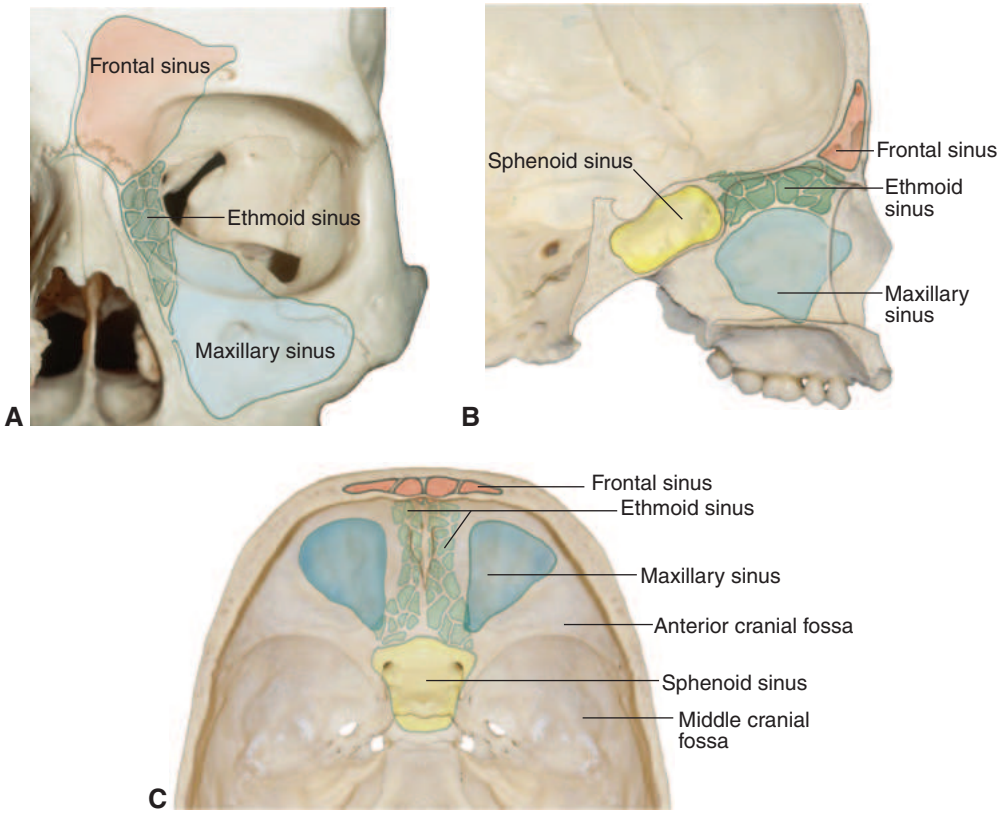

Figure 1-11 Coronal **(A),** sagittal **(B),** and axial **(C)** views of the anatomical relationship of the 4 periorbital sinuses. *(Illustrations by Dave Peace.)*

The *frontal sinuses* develop from evaginations of the frontal recess and cannot be seen radiographically until the sixth year of life. Pneumatization of the frontal bone continues through childhood and is complete by early adulthood. The sinuses can develop asymmetrically and vary greatly in size and shape. Each frontal sinus drains through a separate frontonasal duct and empties into the anterior portion of the middle meatus.

The *ethmoid air cells* are thin-walled cavities that lie between the medial orbital wall and the lateral wall of the nose. They are present at birth and expand throughout childhood. Ethmoid air cells can extend into the frontal, lacrimal, and maxillary bones and may extend into the orbital roof *(supraorbital ethmoids).* The numerous small, thin-walled air cells of the *ethmoid sinus* are divided into anterior, middle, and posterior. The anterior and middle air cells drain into the middle meatus; the posterior air cells into the superior meatus. Bacterial sinusitis in the ethmoids is a common cause of orbital cellulitis and medial subperiosteal abscess when infection spreads into the orbit.

The *sphenoid sinus* evaginates from the posterior nasal roof to pneumatize the sphenoid bone. It is rudimentary at birth and reaches full size after puberty. The sinus drains into the sphenoethmoidal recess of each nasal fossa. The optic canal is located immediately

superolateral to the sinus wall. Pathologic processes involving the sphenoid sinus compress the optic nerve, leading to visual field abnormalities and vision loss.

The *maxillary sinuses* are the largest of the paranasal sinuses. The roof of the maxillary sinus forms the floor of the orbit and extends posteriorly to the inferior orbital fissure. The infraorbital nerve, artery, and vein travel along the roof of the sinus from posterior to anterior. The bony nasolacrimal canal lies within the medial wall. The sinus drains into the middle meatus of the nose by way of the maxillary ostium. Orbital blowout fractures commonly disrupt the floor of the orbit medial to the infraorbital canal, where the bone is thinnest; thus, trauma to the infraorbital nerve often results in hypoesthesia of the cheek, upper lip, and maxillary teeth.

CHAPTER 2

Evaluation of Orbital Disorders

Highlights

- Patient history guides the diagnosis of orbital disorders.
- The evaluation of an orbital disorder should distinguish it from a periorbital or intraocular process.
- Orbital disorders often present with globe displacement; the pattern of observed changes helps determine underlying pathology.
- Orbital disease can be categorized into 5 basic clinical patterns: inflammatory, mass effect, structural, vascular, and functional.
- Computed tomography and magnetic resonance imaging are the primary imaging modalities for orbital disorders.

History

The history of present illness establishes a probable diagnosis and guides the initial workup and therapy. It should include the following:

- onset, course, and duration of symptoms (eg, pain, altered sensation, diplopia, changes in vision) and associated signs (eg, erythema, palpable mass, globe displacement)
- prior disease (eg, thyroid eye disease, sinus disease) and therapy
- injury (eg, head or facial trauma)
- systemic conditions (eg, autoimmune disease, cancer, immunosuppression, thyroid dysfunction)
- family history
- prior photographs of the patient to establish a timeline of the process

Pain

Pain may be a symptom of an inflammatory or infectious process, orbital hemorrhage, malignant lacrimal gland tumors, invasion by a sinonasal carcinoma, or metastatic lesions.

Progression

The rate of progression can be a helpful diagnostic indicator. Conditions with onset occurring over days to weeks include nonspecific orbital inflammation (NSOI), scleritis, myositis, dacryoadenitis, orbital cellulitis, hemorrhage, thrombophlebitis, fulminant neoplasia

(eg, rhabdomyosarcoma, neuroblastoma), and metastatic tumors. Conditions with onset occurring over months to years include dermoid cyst, pleomorphic adenoma of the lacrimal gland, neurogenic tumor, cavernous venous malformation, lymphoma, solitary fibrous tumor, fibrous dysplasia, and osteoma.

Periorbital Changes

Periorbital changes may provide clues to underlying disorders. For example, ecchymosis of the eyelid skin may be a sign of metastatic neuroblastoma (Fig 2-1), leukemia, or amyloidosis. Table 2-1 lists various periorbital signs and their common causes.

Figure 2-1 Left lower eyelid ecchymosis in a child with metastatic neuroblastoma. *(Courtesy of Keith D. Carter, MD.)*

Table 2-1 Periorbital Changes Associated With Orbital Disease

Sign	Etiology
Salmon-colored mass involving fornix and/or bulbar conjunctiva	Lymphoma (see Fig 5-19)
Eyelid retraction and eyelid lag	Thyroid eye disease (see Fig 4-9)
Vascular congestion over the insertions of the rectus muscles (particularly the lateral rectus)	Thyroid eye disease (see Fig 4-8)
Corkscrew conjunctival vessels	Arteriovenous fistula (see Fig 5-5A), carotid-cavernous fistula (see Fig 5-6A)
Vascular anomaly of eyelid skin	Lymphatic malformation, varix (see Fig 5-2A), or infantile hemangioma (see Fig 5-1A)
S-shaped eyelid	Plexiform neurofibroma (see Fig 5-10 and Video 5-1), lacrimal gland mass
Eczematous lesions of the eyelids	Mycosis fungoides (T-cell lymphoma)
Ecchymosis of eyelid skin	Metastatic neuroblastoma (see Fig 2-1), leukemia, amyloidosis
Prominent temple	Sphenoid wing meningioma (see Fig 5-11A), metastatic neuroblastoma
Frozen globe	Metastases, invasive fungal sinusitis (see Fig 4-5A), orbital apex syndrome, cavernous sinus process
Black-crusted lesions	Invasive fungal sinusitis
Facial asymmetry	Fibrous dysplasia (see Fig 5-15A), hemifacial microsomia (see Fig 2-5) neurofibromatosis, Parry-Romberg syndrome

Physical Examination

Special attention should be given to the assessment of visual acuity, pupillary responses, color vision, visual fields, ocular motility, globe position, and the fundus. Diagnostic and imaging studies are often required in addition to the basic workup. Globe displacement is the most common clinical manifestation of an orbital abnormality.

Inspection

Several terms are used to describe the position of the eye and orbit. *Proptosis* or *exophthalmos* denotes a forward displacement or protrusion of the globe. *Exorbitism* refers to an angle between the lateral orbital walls that is greater than 90°, which may also be associated with shallow orbital depth. This condition contrasts with *hypertelorism,* or *telorbitism,* which refers to a wider-than-normal separation between the medial orbital walls. Generally, exorbitism and hypertelorism are congenital or traumatic abnormalities. *Telecanthus* denotes an abnormal increased distance between the medial canthi. The eye may also be displaced vertically (*hyperglobus* or *hypoglobus*) or horizontally by an orbital mass. Retrodisplacement of the eye into the orbit, called *enophthalmos,* may occur because of volume expansion of the orbit (eg, due to fracture or silent sinus syndrome; see Fig 5-26), in association with orbital varix, or secondary to sclerosing orbital tumors (eg, metastatic breast carcinoma; see Fig 5-30).

Because the globe is usually displaced away from the site of a mass, proptosis often indicates the location of that mass. Axial displacement is usually indicative of an intraconal mass behind the globe; such lesions include cavernous venous malformation, optic nerve glioma, primary optic nerve sheath meningioma, metastasis, and arteriovenous malformation (see Chapter 5). Nonaxial displacement is caused by lesions with a prominent component outside the muscle cone. Superior displacement is produced by maxillary sinus tumors invading the orbital floor and pushing the globe upward. Inferomedial displacement can result from orbital dermoid cysts and lacrimal gland tumors. Inferolateral displacement can result from frontoethmoidal mucoceles, abscesses, osteomas, and ethmoid sinus carcinomas.

In adults, bilateral proptosis is most often caused by thyroid eye disease (TED); however, other disorders can also produce bilateral proptosis, including lymphoma, vasculitis, NSOI, metastatic tumors, carotid-cavernous fistulas, cavernous sinus thrombosis, and leukemic infiltrates (see Chapters 4 and 5). TED is also the most common cause of unilateral proptosis in adults. In children with bilateral proptosis, the clinician should consider TED, NSOI, metastatic neuroblastoma, and leukemic infiltrates. Unilateral proptosis in children should raise concern for orbital cellulitis, vascular malformation, and malignancy.

Exophthalmometry is a measurement of the anterior–posterior position of the globe, generally from the lateral orbital rim to the anterior corneal surface (Hertel exophthalmometry, Fig 2-2A). The Naugle exophthalmometer uses the frontal and maxillary bones as its reference structures (Fig 2-2B); this exophthalmometer is useful in trauma patients when the lateral orbital rim has been displaced or in patients who have had the lateral orbital rim removed as part of orbital surgery.

In the absence of disease, globe position varies by age, sex, and race. Mean values are referenced in Black (men: 18.5 mm; women: 17.8 mm) and White (men: 16.5 mm; women: 15.4 mm) populations in the United States. More recent studies have characterized these

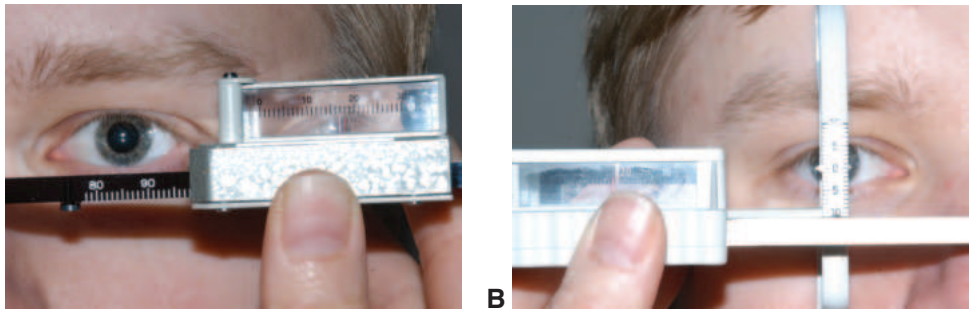

Figure 2-2 Types of exophthalmometers. **A,** The Hertel exophthalmometer uses the lateral orbital rim as its reference point. **B,** The Naugle exophthalmometer uses the frontal and maxillary bones as reference points. It can measure both proptosis and hyperglobus or hypoglobus. *(Courtesy of University of Iowa.)*

Figure 2-3 Worm's-eye-view perspective (also known as submentovertex and Waters view). Note enophthalmos of the right eye. *(Courtesy of Bobby S. Korn, MD, PhD.)*

measurements in particular racial and ethnic groups, including in Hong Kong Chinese (men: 15.3 mm; women: 14.4 mm), Iranians (men: 16.5 mm; women: 16.2 mm), Sinhalese (men: 16.6 mm; women: 15.3 mm), Tamils (men: 16.7 mm; women: 15.0 mm), and Turks (men: 16.1 mm; women: 15.5 mm), among other populations. Asymmetry of greater than 2 mm between an individual patient's eyes suggests proptosis or enophthalmos. These conditions may best be appreciated clinically when the examiner looks up from below, while the patient's head is tilted back; this perspective is called the *submentovertex*, *Waters view,* or *worm's-eye view* (Fig 2-3).

Pseudoproptosis is the simulation of abnormal prominence of the eye or a true asymmetry that is not the result of increased orbital contents. This diagnosis should be reserved until an orbital lesion has been ruled out. Causes of pseudoproptosis include the following:

- enlarged globe or irregular cornea (eg, axial myopia, buphthalmos, staphyloma, keratoconus)
- contralateral enophthalmos (caused by prior orbital trauma, surgery, silent sinus syndrome)
- asymmetric orbital size
- asymmetric palpebral fissures (usually caused by ipsilateral eyelid retraction, facial nerve paralysis, or contralateral blepharoptosis)
- congenital deformity (microphthalmia)

Ocular movements may be restricted in a specific direction of gaze by neoplasm or inflammation. In TED, the inferior rectus is the muscle most commonly affected, resulting in restriction of upgaze and possible hypotropia in primary gaze. A large or rapidly enlarging orbital mass can also impede ocular movements, even in the absence of direct muscle invasion.

Eyelid abnormalities are common in TED. The *von Graefe sign* is a delay in the upper eyelid's descent (eyelid lag) during downgaze and is highly suggestive of TED. In fact, eyelid lag and retraction of the upper and/or lower eyelids are the most common physical signs of TED (see Chapter 4).

Palpation

Palpation around the globe may reveal the presence of a mass in the anterior orbit, especially if the lacrimal gland is enlarged. Increased resistance to retrodisplacement of the globe is a nonspecific abnormality that may result either from a retrobulbar tumor or from diffuse inflammation such as that seen in TED. The physician should also palpate regional lymph nodes.

The differential diagnosis for a palpable mass in the superonasal quadrant may include mucocele, mucopyocele, encephalocele, neurofibroma, dermoid cyst, rhabdomyosarcoma, lymphoma, and amyloid. A palpable mass in the superotemporal quadrant may be a prolapsed lacrimal gland, a dermoid cyst, a lacrimal gland tumor, lymphoma, and NSOI.

Pulsation of the eye is caused by transmission of the vascular pulse through the orbit. This may result from either abnormal vascular flow or transmission of normal intracranial pulsations through a bony defect in the orbital walls. Abnormal vascular flow may be caused by arteriovenous communications, such as carotid-cavernous fistulas. Defects in the bony orbital walls may result from sinus mucoceles, surgical removal of bone, trauma, and developmental abnormalities, including encephalocele, meningocele, and sphenoid wing dysplasia associated with neurofibromatosis type 1.

Primary Studies

Computed tomography (CT) and magnetic resonance imaging (MRI) are the primary studies for evaluation of orbital disorders. Ultrasonography (echography) may also be helpful for some disorders.

Computed Tomography

CT is the most valuable technique for delineating the shape, location, extent, and character of an orbital process (Fig 2-4). CT helps refine the differential diagnosis, and when orbitotomy is indicated, it helps guide the surgical approach by demonstrating the relationship of the lesion to the surgical space or spaces of the orbit (see Fig 7-1). The resolution and soft-tissue contrast of CT are adequate for visualizing nearly all pathologic processes in the orbit, and the bony resolution is superior to that provided by any other modality, making CT the imaging technique of choice for orbital trauma and bony tumors. Orbital CT scans are usually obtained in sections of 2–3 mm. For greater detail, fine cuts at 1.0-mm intervals may be requested.

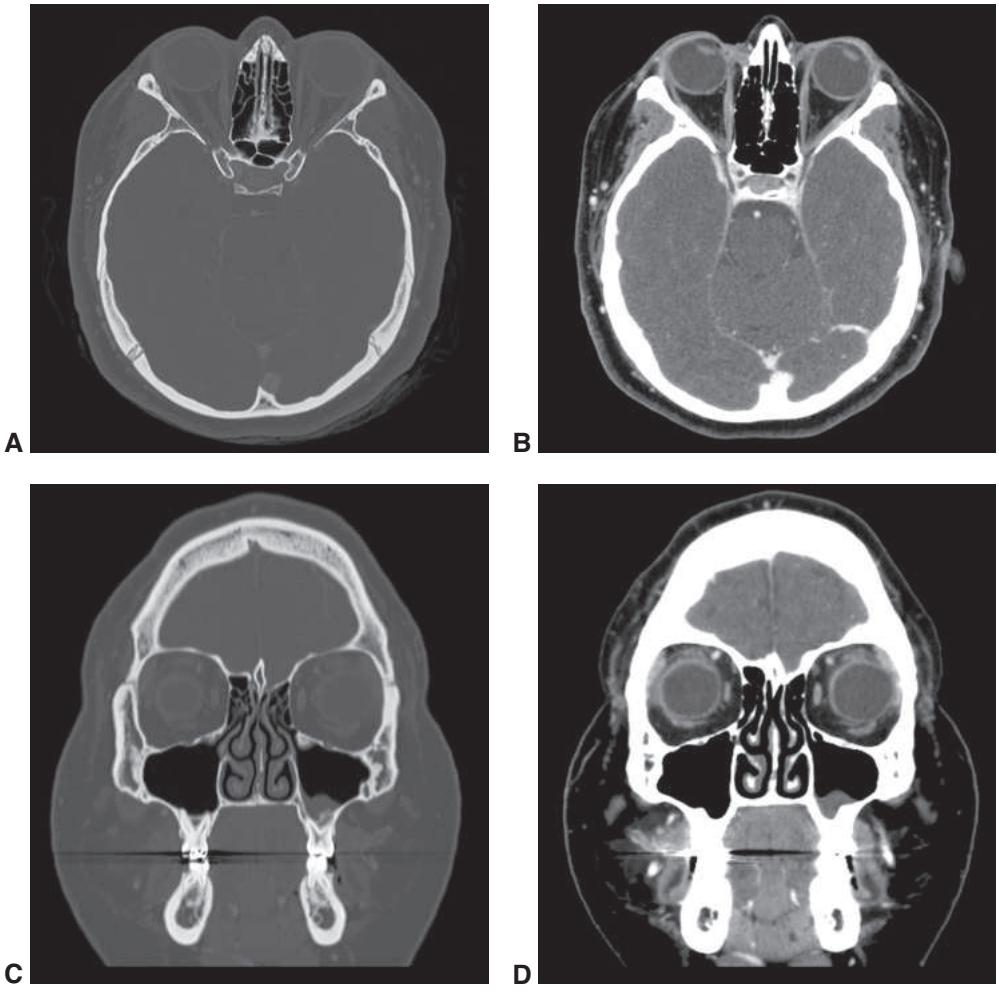

Figure 2-4 Computed tomography (CT) of the orbit, demonstrating normal anatomy. **A,** Axial view with bone window. **B,** Axial view with soft-tissue window. **C,** Coronal view with bone window. **D,** Coronal view with soft-tissue window. *(Courtesy of Steven M. Couch, MD.)*

The visualization of tumors that are highly vascular (eg, meningiomas) or that have altered vascular permeability is improved with use of intravenous contrast-enhancing agents. Contrast is also helpful to identify an orbital abscess. The resolution and tissue-contrast capabilities of CT allow imaging not only of bone but also of soft tissue and foreign bodies. By selecting a particular window type (eg, bone, soft tissue), the CT image gray scale may be manipulated to highlight specific structures.

Orbital images can be obtained in the *axial plane,* parallel to the course of the optic nerve; in the *coronal plane,* which shows the eye, optic nerve, and extraocular muscles in cross section; or in the *sagittal plane,* parallel to the nasal septum. CT scanners use software to reconstruct (reformat) any section in any direction (axial, coronal, or sagittal). *Direct coronal scans* are ideal for evaluation of the optic nerve and extraocular muscles as well as the

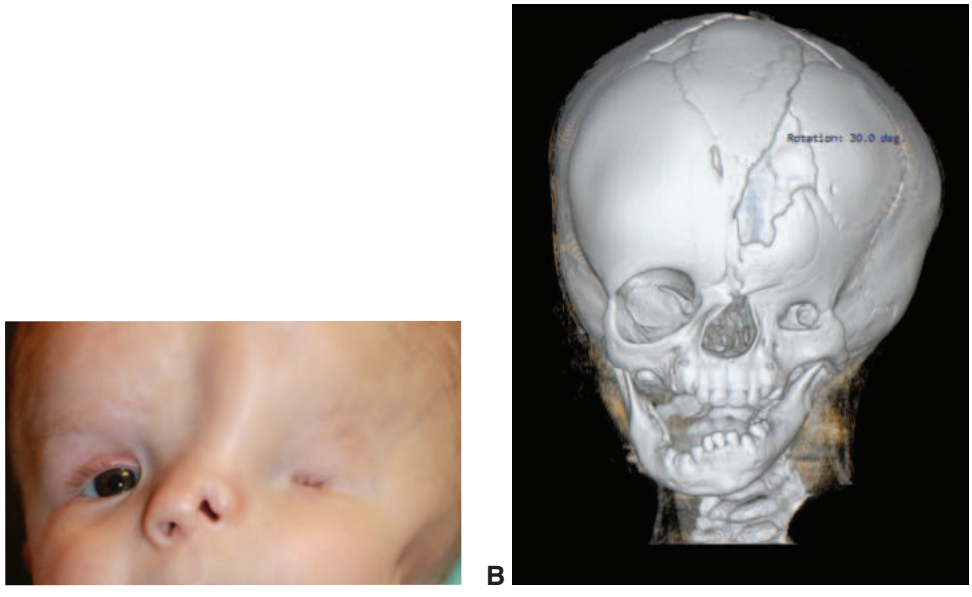

Figure 2-5 Hemifacial microsomia. **A,** Clinical photograph demonstrating left-sided hemifacial microsomia. **B,** Three-dimensional CT reconstruction of same patient. *(Courtesy of Jill A. Foster, MD.)*

bony roof and floor of the orbit. *Three-dimensional CT* allows reformatting of CT information into 3-dimensional projections of the bony orbital walls (Fig 2-5). Because this type of imaging requires thin sections and additional computer time, it is typically reserved for use in preparation for craniofacial surgery or repairs of complex orbital fractures.

Magnetic Resonance Imaging

MRI is a noninvasive imaging technique that does not employ ionizing radiation and has no known adverse biological effects (Fig 2-6). MRI is based on the interaction of 3 physical components: atomic nuclei, which possess an electrical charge; radiofrequency (RF) waves; and a powerful magnetic field.

Each orbital tissue has specific magnetic resonance (MR) parameters that provide the information used to generate an image. These parameters include a tissue's proton density and relaxation times. *Proton density* is determined by the number of protons per unit volume of tissue. Each tissue has different proton density and T1 (longitudinal relaxation time) and T2 (transverse relaxation time) characteristics, which provide the image the contrast necessary to differentiate tissues. Healthy tissue can have imaging characteristics different from those of diseased tissue, a good example being the bright signal associated with tissue edema seen on T2-weighted scans.

MRI is usually performed with images created from both T1 and T2 parameters. T1-weighted images generally offer the best anatomical detail of the orbit. T2-weighted images have the advantage of demonstrating methemoglobin as brighter than melanin, whereas these substances have the same signal intensity on T1-weighted images. The difference in brightness seen on T2-weighted images can be helpful in differentiating melanotic lesions

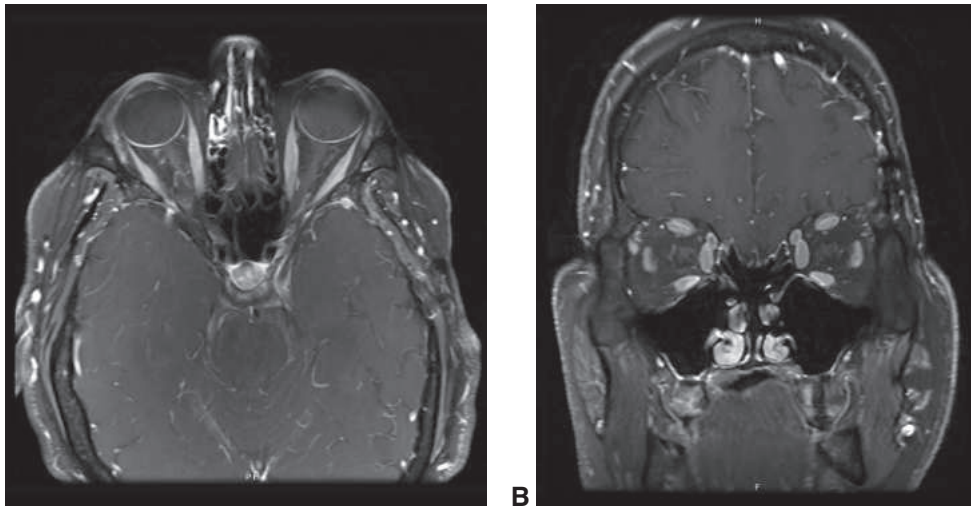

Figure 2-6 Gadolinium-enhanced T1-weighted magnetic resonance imaging of the orbit, with fat suppression; normal anatomy is demonstrated. **A,** Axial view. **B,** Coronal view. *(Courtesy of M. Reza Vagefi, MD.)*

from hemorrhagic processes. *Gadolinium,* a paramagnetic contrast agent given intravenously, allows enhancement of vascularized lesions so that they exhibit the same density as fat. It also enhances lesions that have abnormal vascular permeability. Special MR sequences have been developed to suppress the normal bright signal of fat on T1-weighted images ("fat suppression"; see Fig 2-6) and the bright signal of cerebrospinal fluid on T2-weighted images (fluid-attenuated inversion recovery, or FLAIR). *Gradient echo sequences* may reveal hemorrhage in vascular malformations that might be missed on T1- and T2-weighted images. *Diffusion weighted imaging (DWI) sequences* may assist in the assessment of local tissue perfusion, such as optic nerve infarction, or in distinguishing different orbital lesions.

Comparison of CT and MRI

Although both CT and MRI are important modalities for the detection and characterization of orbital and ocular diseases, CT is currently the primary and most useful orbital imaging technique. Compared with MRI, it is faster, less expensive, and less sensitive to motion artifact. In general, CT provides better spatial resolution (differentiation between 2 objects near each other), allowing precise localization of a lesion. MRI generally provides better tissue contrast than CT; however, in most orbital disorders, the orbital fat provides sufficient natural tissue contrast to readily allow visualization of orbital tumors on CT. Each of the techniques has advantages in specific situations, some of which are discussed in the following text and in Table 2-2.

MRI offers advantages over CT in some situations. It allows the direct display of anatomical information in multiple planes (sagittal, axial, coronal, and any oblique plane).

Table 2-2 Comparison of CT and MRI in Orbital Disease

CT	MRI
Good technique for most orbital conditions, especially trauma and TED	Better technique for orbitocranial junction or intracranial imaging
Good view of bone and calcium	No view of bone or calcification
Limited definition of the orbital apex	Good view of orbital apex soft tissues unimpeded by bone
Better spatial resolution	More soft-tissue detail
Reformatting or rescanning required to image in multiple planes	Simultaneous imaging of multiple planes
Improved imaging with contrast, in many cases	Improved imaging with contrast, in many cases
Less potential for motion artifact because of shorter scanning time	More potential for motion artifact because of longer scanning time
Less claustrophobic environment in scanner	Tighter confines in closed MRI; open MRI scanners are available but have lower resolution
Preferred technique for patients who may have metallic foreign bodies	More contraindications (eg, patients with ferromagnetic metallic foreign bodies, aneurysm clips, pacemakers)
Contraindicated in pregnancy; use should be limited in children	Can be used safely in pregnant women and children
Less expensive technique	More expensive technique
Contrast contraindicated in patients with allergy to iodine or with renal dysfunction	Use of gadolinium carries risk of nephrogenic systemic fibrosis in patients with severe renal failure (stage 4 or 5; GFR <30 mL/min/1.73 m^2)

CT = computed tomography; GFR = glomerular filtration rate; MRI = magnetic resonance imaging; TED = thyroid eye disease.

In addition, MRI provides better soft-tissue definition than does CT, a capability that is especially helpful in the evaluation of demyelination as well as vascular and hemorrhagic lesions (Fig 2-7).

MRI also provides better tissue contrast of structures in the orbital apex, including the intracanalicular portion of the optic nerve, structures in periorbital spaces, and orbitocranial tumors, because there is no artifact from the skull-base bones. Bone and calcification produce a low signal on MRI, and thus bony structures may be evaluated by visualization of the signal void left by the bone. However, this is not possible when the bone is adjacent to structures and elements that also create a signal void, such as air, rapidly flowing blood, calcification, and dura mater. Thus, CT is superior to MRI for the evaluation of fractures, bone destruction, hyperostosis, and tissue calcification.

MRI is contraindicated in patients who have ferromagnetic metallic foreign bodies in the orbit or periorbital soft tissue. Special considerations need also to be made in the presence of ferromagnetic vascular clips, magnetic intravascular filters, or electronic devices in the body such as cardiac pacemakers or deep brain stimulators. A history of prior procedural or surgical intervention should be elicited, and if necessary, the presence of such

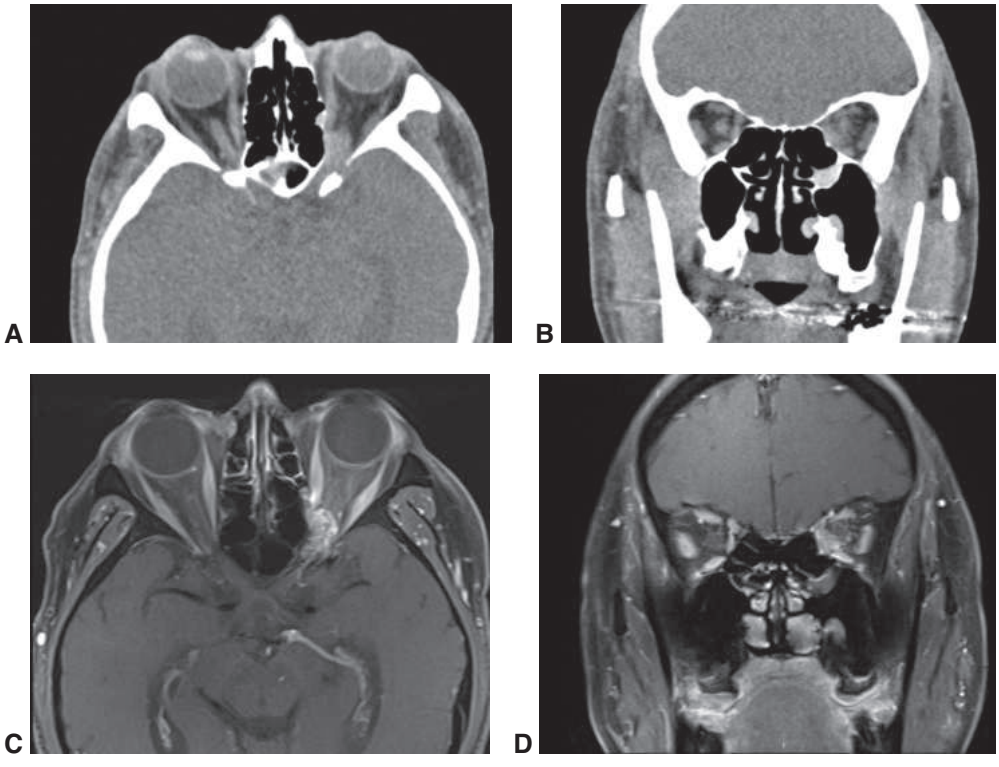

Figure 2-7 Arteriovenous malformation (AVM) of the left orbit. **A,** Axial CT image postcontrast with soft-tissue window demonstrates a heterogeneously enhancing intraconal process of the left orbital apex. **B,** Coronal CT image postcontrast with soft-tissue window shows an intraconal process that is difficult to delineate from the extraocular muscles and optic nerve. **C,** Axial T1-weighted magnetic resonance (MR) image postcontrast with fat suppression clearly demonstrates an enhancing, heterogeneous lesion of the left orbital apex with intracranial extension through the superior orbital fissure consistent with an AVM. Note the improved soft tissue resolution. **D,** Coronal T1-weighted MR image postcontrast with fat suppression shows that the AVM lies inferomedial to the optic nerve and has displaced it in a superolateral direction. *(Courtesy of Lilangi Ediriwickrema, MD.)*

foreign material can be ruled out with plain film x-ray or CT. Certain types of eye makeup can produce artifacts and should be removed prior to MRI. Dental amalgam is not a ferromagnetic substance and is not a contraindication to MRI, but this material produces artifacts and degrades the images on both MRI and CT. Titanium is paramagnetic, and thus patients with orbital, facial, or cranial hardware may safely have an MRI. Similarly, implanted eyelid weights composed of pure gold, pure platinum, or platinum/iridium alloy are MRI compatible with a magnetic field strength up to 7.0 Tesla.

Because CT and MRI yield different types of images, it is not unusual for both techniques to be employed in the evaluation of complex orbital disorders. The use of these modalities should be based on the patient's specific condition. In general, MRI is the better primary technique for imaging the orbitocranial junction and brain; however, CT scanning may enhance the assessment by providing superior bone visualization.

CT imaging should be obtained judiciously in children, as they are much more radiosensitive than adults. Extrapolation of lifetime risk of malignancy development in atomic bomb survivors led to a consensus statement from the American Academy of Pediatrics that low-level radiation may carry a small risk of cancer. When possible, MRI should be considered as the study of choice for children, with CT reserved for select clinical scenarios.

Leung RS. Radiation protection of the child from diagnostic imaging. *Curr Pediatr Rev*. 2015;11(4):235–242.

Stereotactic Navigation

The use of computer-assisted 3-dimensional navigation (image guidance) is increasingly common in clinical practice (Fig 2-8). Stereotactic guidance can be useful for complex multidisciplinary surgical procedures in which orbital lesions are accessed through craniotomy and endoscopic skull-base approaches. However, in uncomplicated orbital surgery, while image guidance may have some utility for surgical training, it has a lesser role in procedures performed by experienced orbital surgeons.

Ultrasonography

Orbital ultrasonography may be used to examine patients with orbital disorders. The size, shape, and position of normal and abnormal orbital tissues can be determined by means of contemporary ultrasound techniques. B-scan ultrasonography captures 2-dimensional images of these tissues, while standardized A-scan ultrasonography provides 1-dimensional images rendered as a series of spikes of varying height and width that demonstrate the particular echogenic characteristics of each tissue. Areas of edema can sometimes be used to discern the degree of disease activity; ultrasonography has high resolution in the area of the sclera and optic nerve insertion and is useful for evaluating scleritis and other types of anterior inflammation that produce fluid in the sub-Tenon space. Localization of foreign bodies is possible

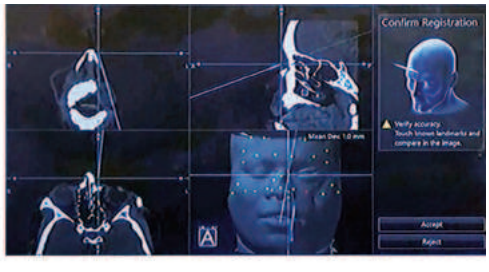

Figure 2-8 Computer-assisted 3-dimensional navigation (image guidance). Placement of the probe *(left)* allows real-time visualization of relevant anatomy on preoperatively acquired imaging *(right)*. *(Courtesy of M. Reza Vagefi, MD.)*

with ultrasonography. *Doppler ultrasonography* can provide specific information regarding blood flow and can demonstrate arterialization, retrograde flow in the orbital veins in cases of dural cavernous fistula or arteriovenous malformation, and vascular abnormalities associated with increased blood flow. Vascular tumors can be identified by active pulsation or, in the case of venous lesions, by compressibility and change in size with the Valsalva maneuver.

Ultrasound analysis of orbital tissues and diseases requires specialized equipment and experienced personnel; office-based equipment is generally not suitable for this purpose. Moreover, ultrasonography is of limited value in assessing lesions of the posterior orbit (because of sound attenuation), the sinuses, or intracranial space (because sound does not pass well through air or bone).

Secondary Studies

Secondary studies that are performed for specific indications include venography, arteriography, and stereotactic navigation. Although these studies are rarely used, they may be helpful in specific cases.

Venography

Before the advent of CT and MRI, orbital venography, in which contrast material is injected into the frontal or the angular vein to reveal a venous abnormality, was used in the diagnosis and management of orbital varices and in the study of the cavernous sinus. Subtraction and magnification techniques have been used to increase the resolution of venography. Because moving blood generates a signal void during MR imaging, larger venous abnormalities and structures can be visualized well on MR venography. Some orbitocranial vascular malformations and fistulas are best accessed directly via the superior ophthalmic vein, both for diagnosis and for possible treatment.

Arteriography

Arteriography is the gold standard for diagnosis of an arterial lesion such as an aneurysm, arteriovenous malformation (AVM), and carotid-cavernous fistula. Retrograde catheterization of the cerebral vessels is performed through the femoral artery. However, there is a small risk of serious neurologic and vascular complications (1%–2%) because the technique requires installation of a catheter and injection of radiopaque dye into the arterial system; thus, the test is reserved for patients with a high probability of having a lesion.

Visualization can be maximized with selective injection into the internal and external carotid arteries, magnification to allow viewing of the smaller-caliber vessels, and subtraction techniques to radiographically eliminate bone. An additional benefit of arteriography is the ability to simultaneously diagnose and embolize lesions with use of various glues and coils.

CT and MR Angiography

The development of modern hardware and software has enabled precise CT and MR imaging for diagnosis of arteriovenous malformations, aneurysms, and arteriovenous fistulas

without the expense, discomfort, and risks associated with the use of contrast agents and intravascular catheterization. *Time-resolved imaging of contrast kinetics (TRICKS)* uses extremely rapid acquisition of MRIs to provide dynamic images of intravascular contrast flow and may assist in the evaluation of orbital vascular lesions. MR angiography is also useful for diagnosis of vascular compression of the facial nerve at the root exit zone that results in hemifacial spasm. However, MR angiography is less sensitive than direct catheter angiography for identifying carotid-cavernous fistulas. When determining which test to use, the ophthalmologist may consult with a neuroradiologist to discuss the suspected lesion and to ensure selection of the imaging modality best suited to the patient.

Ramey NA, Lucarelli MJ, Gentry LR, Burkat CN. Clinical usefulness of orbital and facial Time-Resolved Imaging of Contrast KineticS (TRICKS) magnetic resonance angiography. *Ophthalmic Plast Reconstr Surg.* 2012;28(5):361–368.

Pathology

The diagnosis of an orbital lesion usually requires analysis of tissue obtained through an orbitotomy. Appropriate handling of the tissue specimen is necessary to ensure an accurate diagnosis. Most tissue samples are placed in formalin for permanent section analysis. Frozen section evaluation may be performed at the time of surgery, but it is generally not used for definitive diagnosis of an orbital tumor. However, when the area of proposed biopsy is not obvious, frozen sections are helpful to confirm that appropriate tissue has been obtained for permanent section analysis. Frozen section analysis is also used intraoperatively to determine tumor margins and ensure complete tumor removal. Tissue removed for frozen section analysis should be placed in a dampened saline gauze and sent promptly for analysis.

Preoperative consultation with a pathologist familiar with orbital disease may be helpful to maximize the information gained from an orbital biopsy. In many cases, fresh tissue should be obtained for frozen section and cell-surface-marker studies. Cell-marker studies (flow cytometry and immunohistochemistry) are required in the analysis of all orbital lymphoid lesions. These studies may allow differentiation between reactive lymphoid hyperplasia and lymphoma. Such studies may also indicate the presence of estrogen receptors in cases of metastatic prostate or breast carcinoma and thus provide useful information about sensitivity to hormonal therapy. Marker studies are also helpful in the diagnosis of poorly differentiated tumors when light microscopy alone is not definitive.

All biopsy specimens must be treated delicately to minimize crush and cautery artifacts, which can limit interpretation. Permanent section tissue biopsy specimens should be placed in fixatives promptly. If fine-needle aspiration biopsy is planned, a cytologist or trained technician must be available to handle the aspirate (see Fig 7-13). In special cases, the biopsy can be performed under either ultrasonographic or CT guidance. Although a fine-bore needle occasionally yields a sufficient cell block, the specimen is usually limited to cytologic study. Larger biopsy specimens, in which light and electron microscopy can be used to evaluate histologic patterns, may permit a more conclusive diagnosis.

Genomic analysis of tumors is more frequently being performed; this modality has implications for disease prognosis and the use of targeted therapies.

See BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors,* for a more extensive discussion of pathology.

Laboratory Studies

For suspected TED, screening for abnormal thyroid function commonly includes free T_4 and thyroid-stimulating hormone (TSH) tests. Results of these serum tests are abnormal in 90% of patients with TED. However, if the results are normal but thyroid disease is still strongly suspected, additional endocrine studies, such as of thyroid-stimulating immunoglobulins or TSH-receptor antibodies, can be considered, as these tests have greater sensitivity for detecting autoimmune thyroid disease.

Granulomatosis with polyangiitis (GPA; see Chapter 4) should be considered in patients with sclerokeratitis or coexisting sinus and/or orbital disease. A useful test for GPA is the antineutrophil cytoplasmic autoantibody (ANCA) serum assay, which demonstrates a cytoplasmic staining pattern (c-ANCA). It should be noted that studies have found the sensitivity of c-ANCA testing for isolated sino-orbital GPA to be significantly lower than in generalized GPA. Biopsy of affected tissues is often critical in establishing diagnosis and classically shows vasculitis, granulomatous inflammation, and tissue necrosis, although necrotizing vasculitis is not always present in orbital biopsies.

Sarcoidosis is a multisystem granulomatous inflammatory condition that may present with lacrimal gland enlargement, conjunctival granulomas, extraocular muscle or optic nerve infiltration, and/or solitary orbital granulomas. While testing with serum angiotensin-converting enzyme (ACE) and lysozyme may be helpful in the diagnosis of systemic sarcoid, investigations have demonstrated that ACE and lysozyme levels are often normal in isolated orbital disease. Diagnosis is thus facilitated with tissue biopsy.

CHAPTER 3

Congenital Orbital Anomalies

This chapter includes related videos. Go to www.aao.org/bcscvideo_section07 or scan the QR codes in the text to access this content.

Highlights

- Anophthalmia is rare and is usually associated with lethal pathogenic variants.
- Rehabilitation in microphthalmia is directed toward expansion of the hypoplastic orbit.
- Craniofacial clefts result from developmental arrest or mechanical disruption of development.
- Craniosynostosis occurs as an isolated abnormality or as part of a genetic syndrome.
- When symptomatic, dermoid cysts should be removed with the cyst wall intact.

Introduction

Developmental defects of the orbit can manifest clinically at any time from conception until late life. Most significant congenital anomalies of the eye and orbit are apparent on prenatal ultrasonography. The more profound the abnormality, the earlier in development it occurred. Identifying the embryologic origin of the congenital malformation helps ophthalmologists understand and classify the physical changes in the patient.

If an anomaly is caused by a slowing or cessation of a normal stage of development, the resulting deformity can be considered a pure arrest.

In the examination of a child with an ocular or craniofacial malformation, the clinician should focus on carefully defining the severity of the defect and identifying associated changes. Some syndromes may have specific associated ocular changes or secondary ocular complications, such as exposure keratitis or strabismus related to orbital maldevelopment.

See Section 6, *Pediatric Ophthalmology and Strabismus,* for detailed discussion and illustrations of many of the topics covered in this chapter.

Anophthalmia

True anophthalmia is defined as a total absence of tissues of the eye; it is classified into 3 types. *Primary anophthalmia,* which is rare and usually bilateral, occurs when the primary optic vesicle fails to grow out from the cerebral vesicle at the 2-mm stage of embryonic

development. *Secondary anophthalmia* is rare and lethal and results from a gross abnormality in the anterior neural tube. *Consecutive anophthalmia* results from a secondary degeneration of the optic vesicle.

Because orbital development is partially dependent on the size and growth of the globe, the bones of the orbit and adnexal structures fail to develop and remain hypoplastic in anophthalmia. Intervention requires measures that address all these issues, not just the absent eye.

Plaisancié J, Ceroni F, Holt R, et al. Genetics of anophthalmia and microphthalmia. Part 1: Non-syndromic anophthalmia/microphthalmia. *Hum Genet.* 2019;138(8–9):799–830.

Slavotinek A. Genetics of anophthalmia and microphthalmia. Part 2: Syndromes associated with anophthalmia-microphthalmia. *Hum Genet.* 2019;138(8–9):831–846.

Microphthalmia

Microphthalmia is much more common than anophthalmia and is defined by the presence of a small eye with an axial length that is at least 2 standard deviations below the mean axial length for age. Microphthalmic eyes vary in size depending on the severity of the defect. Most infants with a unilateral small orbit (Fig 3-1) and no visible eye have a microphthalmic globe. The defect may be isolated, or it may occur with a constellation of abnormalities as part of a well-defined syndrome. Because multiple genetic pathogenic variants have been reported in anophthalmia/microphthalmia, microphthalmia is considered a developmental phenotype that results from several different genetic rearrangements.

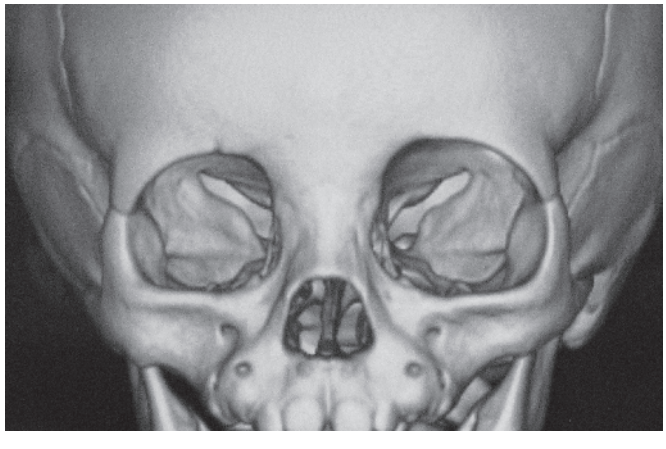

Figure 3-1 Right microphthalmic orbit. Three-dimensional computed tomography (CT) reconstruction demonstrates a hypoplastic right orbit with microphthalmia. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Treatment of Anophthalmia/Microphthalmia

All children with microphthalmia have hypoplastic orbits. Because most microphthalmic eyes have no potential for vision, treatment focuses on achieving a cosmetically acceptable appearance that is reasonably symmetric. Treatment begins shortly after birth

and consists of socket expansion with progressively larger conformers, which are used until socket expansion is complete and the patient can be fitted with a prosthesis. Enucleation is usually not necessary for the fitting of a conformer or an ocular prosthesis and is ordinarily avoided because it may worsen the bony hypoplasia. Orbital volume may be augmented with autogenous tissue, such as a dermis-fat graft, or with a synthetic implant. When placed at an early age, a dermis-fat graft may grow with the child, resulting in progressive socket expansion.

Craniofacial techniques have been used to reposition and resize the orbit in patients with severe microphthalmia or anophthalmia and in older children with previously untreated microphthalmia. Such repairs are complex, as noted in the following discussion of craniofacial clefting.

Microphthalmia with orbital cyst results from failure of the choroidal fissure to close in the embryo (Fig 3-2). This condition is usually unilateral but may be bilateral. The presence of an orbital cyst may be beneficial for stimulating normal growth of the involved orbital bone and eyelids. In some cases, the orbital cyst may be removed to allow the fitting of an ocular prosthesis. When these conditions are bilateral, significant visual impairment can result. Prompt referral for low vision rehabilitation and early intervention should be initiated in infancy.

Craniofacial Clefting and Syndromic Congenital Craniofacial Anomalies

Craniofacial clefts occur because of a developmental arrest or mechanical disruption of development. Etiologic theories include a failure of neural crest cell migration and a failure of fusion or movement of facial processes. Facial clefts in the skeletal structures are distributed around the orbit and maxilla (Fig 3-3). Clefts in the soft tissues are most apparent around the eyelids and lips (Fig 3-4). Examples of clefting syndromes affecting the orbit and eyelids include forms of midline clefts with hypertelorism as well as craniofacial microsomia and oculo-auriculo-vertebral spectrum, which comprises oculo-auriculo-vertebral disorder, hemifacial microsomia (see Fig 2-5), and Goldenhar syndrome (Fig 3-5). Mandibulofacial dysostosis (Treacher Collins syndrome) is another rare genetic disorder characterized by distinctive craniofacial abnormalities (Fig 3-6).

The bones of the skull or orbit may also have congenital clefts through which intracranial contents can herniate. These protruding contents can be the meninges *(meningocele),* brain tissue *(encephalocele),* or both meninges and brain tissue *(meningoencephalocele).* When these herniations involve the orbit, they most commonly present anteriorly with a protrusion subcutaneously near the medial canthus or over the bridge of the nose. Straining or crying may increase the size of the mass, and the globe may be displaced temporally and inferolaterally. Such herniations less commonly move into the posterior orbit. However, when present, these lesions may cause anterior displacement and pulsation of the globe. Intranasal extension may occur, causing life-threatening airway obstruction. Treatment is surgical and should be carried out in collaboration with neurosurgery and craniofacial surgery. Meningoceles and encephaloceles adjacent to the orbit are frequently associated with anomalies of the optic nerve head, such as morning glory disc anomaly.

Craniosynostosis can occur as an isolated abnormality or in conjunction with other anomalies as part of a genetic syndrome. *Syndromic craniosynostosis* is the premature closure of 1 or more sutures in the bones of the skull and results in various skeletal deformities, including orbital defects. Associated ophthalmic problems include strabismus, astigmatism, blepharoptosis, proptosis, nasolacrimal duct obstruction, and amblyopia. Secondary intracranial hypertension can be a complication. Hypertelorism and proptosis are frequently observed in craniosynostosis syndromes such as craniofacial dysostosis (Crouzon syndrome; Fig 3-7) and acrocephalosyndactyly type 1 (Apert syndrome; Fig 3-8). Syndromic craniosynostosis is a genetically heterogeneous disorder, with pathogenic variants identified in several genes, predominantly the fibroblast growth factor receptor genes.

The severe orbital and facial defects associated with craniofacial disorders can sometimes be improved with surgery. Bony and soft tissue reconstruction is generally necessary. Such operations are often staged and usually require a multidisciplinary approach.

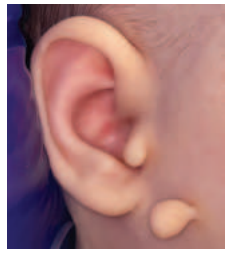
A



B

Figure 3-5 Goldenhar syndrome is part of the oculo-auriculo-vertebral spectrum and can manifest with a host of craniofacial abnormalities. **A,** (Left) upper eyelid coloboma, lateral dermolipoma (of the left eye), and inferotemporal limbal dermoid (of the right eye) are characteristic ophthalmic findings and can occur on either side. **B,** Preauricular skin tags may also be observed, in addition to an absent or malformed ear (not pictured). *(Courtesy of Cat N. Burkat, MD.)*

Figure 3-6 Mandibulofacial dysostosis (Treacher Collins syndrome) is a rare genetic disorder characterized by craniofacial abnormalities of varying degree, including hypoplastic or absent zygomatic malar complex that results in periocular changes with downward-slanting palpebral fissures. Lower eyelid colobomas may also be present. Mandibular hypoplasia causes micrognathia with the characteristically small chin and lower jaw. Abnormalities of the external and middle ear are also found, manifesting as absent, small, or malformed ears and conductive hearing loss. *(Courtesy of Nicholas Mahoney, MD.)*

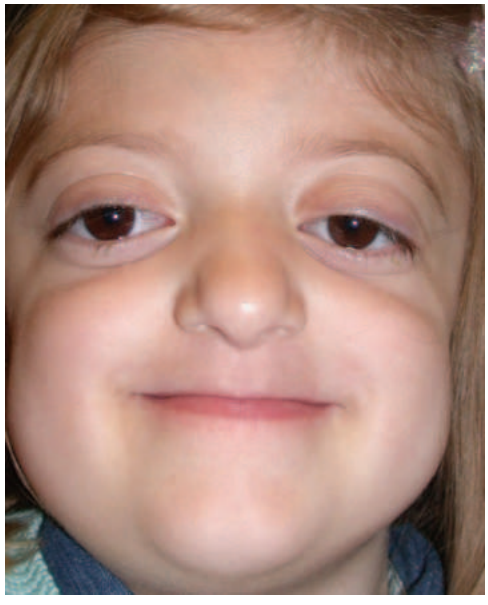


Figure 3-7 Craniofacial dysostosis (Crouzon syndrome) is a rare, genetic craniosynostosis syndrome characterized by hypertelorism, shallow orbits, and resultant proptosis. Frontal bossing, a curved nose, hypoplastic maxilla, and relative protrusion of the lower jaw may also be observed. *(Courtesy of Jill Foster, MD.)*

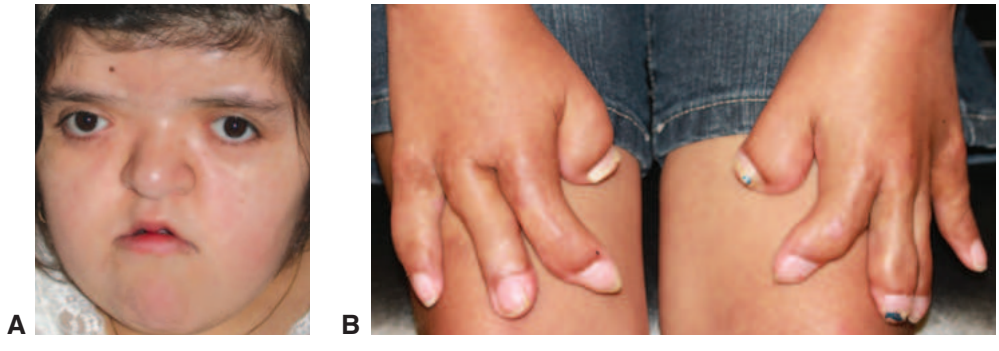

Figure 3-8 Acrocephalosyndactyly type 1 (Apert syndrome) is a rare, genetic craniosynostosis syndrome that results in anomalies of the skull, face, and limbs. **A,** Characteristic ophthalmic findings include hypertelorism, proptosis, and downward-slanting palpebral fissures. A flattened nose with a low bridge and maxillary hypoplasia may also be present. **B,** Distinctive hand and foot abnormalities include syndactyly with partial or complete fusion of the digits. Short fingers and broad thumbs are also typical findings. *(Courtesy of Jill Foster, MD.)*

Congenital Orbital Tumors

Hamartomas and Choristomas

Hamartomas are anomalous growths of tissue consisting only of mature cells normally found at the involved site. Classic examples are infantile (capillary) hemangiomas and the characteristic lesions of neurofibromatosis. *Choristomas* are tissue anomalies characterized by types of cells not normally found at the involved site. Classic examples are dermoid cysts, epidermoid cysts, dermolipomas (lipodermoids), and teratomas. This chapter discusses only some

of the choristomas; further discussion of these congenital and juvenile tumors can be found in BCSC Section 6, *Pediatric Ophthalmology and Strabismus.*

Dermoid cyst

Dermoid and epidermoid cysts are among the most common benign orbital tumors diagnosed in children. These cysts are present congenitally and enlarge progressively. The more superficial cysts usually become symptomatic in childhood, but deeper orbital dermoids may not become clinically evident until adulthood. *Dermoid cysts* are lined by keratinizing epithelium and contain dermal appendages, such as hair follicles and sebaceous glands, and contain an admixture of oil and keratin. In contrast, *epidermoid cysts* are lined by epidermis only and are usually filled with keratin; they do not contain dermal appendages.

Orbital dermoid cysts most commonly occur in the lateral brow, adjacent to the frontozygomatic suture (Fig 3-9A); less often they may be found in the medial upper eyelid, adjacent to the frontoethmoidal suture. Dermoid cysts typically present as palpable, smooth, painless oval masses that enlarge slowly. They may be freely mobile, or they may be fixed to periosteum at the underlying suture.

If the dermoid occurs in the temporal fossa, computed tomography (CT) is often indicated to rule out dumbbell-shaped expansion through the suture into the underlying orbit. A "dumbbell dermoid cyst" such as this can cause pulsating proptosis with mastication, a highly specific feature of this condition.

CT is also useful to evaluate medial lesions and to distinguish dermoids from congenital encephaloceles, dacryoceles, and vascular lesions that might also occur in this location. When viewed on a CT scan, an orbital dermoid cyst is typically well defined by an enhancing wall and a nonenhancing lumen (Fig 3-9B). A partially calcified margin or rim is visible in most cases. With magnetic resonance imaging (MRI), the lesion is best appreciated on fat-suppression sequences and appears as a well-defined round or ovoid structure of variable size. Most dermoids are relatively hypointense with respect to orbital fat on T1-weighted images and relatively hyperintense on T2-weighted images. Enhancement is minimal because of the lack of blood vessels in the cyst.

Dermoid cysts that do not present until adulthood are often not palpable because they are situated posteriorly in the orbit, usually in the superior and temporal portions, adjacent to the bony sutures. The globe and adnexa may be displaced, causing progressive proptosis. Long-standing dermoid cysts may result in erosion or remodeling of the orbital bones. In some cases, the clinical presentation may be of orbital inflammation, which is incited by leakage of oil and keratin from the cyst. Expansion of the dermoid cyst and inflammatory response to the leaked cyst contents may ultimately result in an orbitocutaneous fistula. A fistula may also occur after incomplete surgical removal.

Management Dermoid cysts are usually removed surgically (Figs 3-9C, 3-9D; Videos 3-1 and 3-2). Because dermoid cysts that present in childhood are often superficial, they can be excised through an incision placed in the upper eyelid crease or directly over the lesion. If possible, the cyst wall should be maintained during surgery. Rupture of the cyst can lead to an acute inflammatory process if part of the cyst wall or any of the contents remain within the eyelid or orbit. If the cyst wall is ruptured, the surgeon should remove the cyst contents.

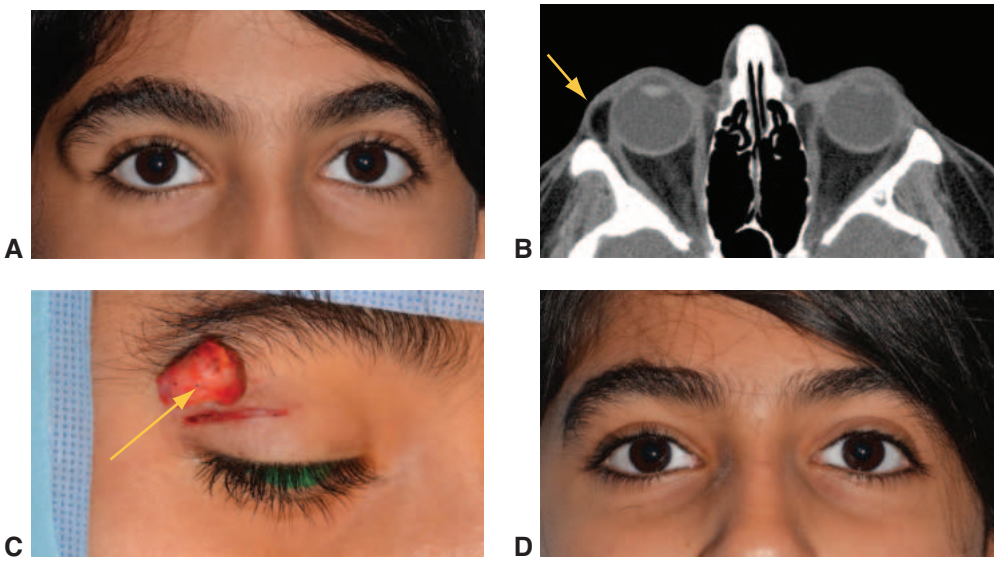

Figure 3-9 Orbital dermoid cyst. **A,** Child with fullness of the right superolateral orbit. **B,** CT scan of the hypointense lesion *(arrow)* in the axial plane is characteristic of a dermoid cyst (epithelial choristoma); note its location at the frontozygomatic suture line. **C,** Dermoid cyst removed through an upper eyelid crease incision shows dermal appendages *(arrow)*. **D,** Postoperative photograph shows resolution of the eyelid fullness. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Complete surgical removal may be difficult if the cyst has leaked preoperatively and adhesions have developed.

VIDEO 3-1 Excision of lateral dermoid.

Dermolipoma

Dermolipomas (lipodermoids) are solid tumors that predominantly consist of mature adipose tissue and are usually located in and beneath the conjunctiva over the globe's lateral surface. These benign lesions may have deep extensions that can abut the levator aponeurosis and/or extraocular muscles. Superficially, dermolipomas may have fine hairs that can be irritating to patients (Fig 3-10). These tumors typically require no treatment unless the lesion is large and/or cosmetically objectionable. In these cases, only the anterior, visible portion should be excised; when possible, the overlying conjunctiva should be preserved. Care must be taken to avoid damage to the lacrimal gland ducts, extraocular muscles, and the levator aponeurosis. Lesions that may simulate dermolipomas include prolapsed orbital fat, a prolapsed palpebral lobe of the lacrimal gland, and lymphoma—processes that are generally found only in adults.

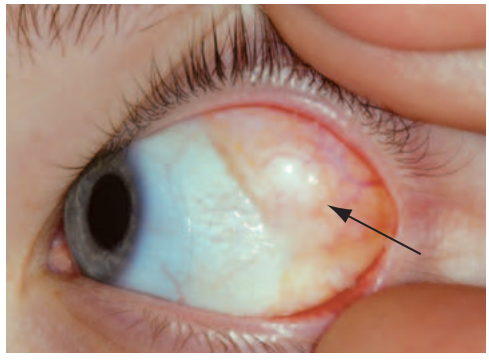

Figure 3-10 Dermolipoma of left lateral orbit. Adipose tissue and fine hairs are noted on the surface of the tumor *(arrow).* *(Courtesy of Keith D. Carter, MD.)*

Teratoma

Teratomas are rare tumors that arise from all 3 germinal layers (ectoderm, mesoderm, and endoderm) and are usually cystic. On histologic examination, a teratoma is characterized by a complex arrangement of various tissues, including clear cysts lined by either epidermis or gastrointestinal or respiratory epithelium, and islands of hyaline cartilage, cerebral tissue, epidermal cysts, and choroid plexus are frequently found. A child with an orbital teratoma characteristically presents with severe unilateral proptosis at birth. Consequently, the globe and optic nerve may be maldeveloped. When the tumor is small, the globe is often normal. The proptosis may increase over the first few days or weeks of life, and compression of the globe can result in corneal exposure and vision loss. Resection can be performed to preserve ocular function. Although teratomas in other parts of the body have been known to undergo malignant transformation, those confined to the orbit are generally benign. However, exenteration may be necessary for those that are malignant.

CHAPTER 4

Orbital Inflammatory and Infectious Disorders

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- Orbital inflammatory disease comprises a broad range of disorders that can be divided conceptually into those that have an identifiable cause (specific) and those that do not (nonspecific).
- All specific causes of orbital inflammation, such as infections or autoimmune diseases, must be eliminated before a diagnosis of nonspecific orbital inflammation is applied.
- This chapter presents an overview of the major causes of orbital inflammation, with the goal of providing a working knowledge of the most common of these disorders (Table 4-1).

Infectious Inflammation

Cellulitis

Most cases of cellulitis stem from bacterial infection; however, cellulitis that results from noninfectious (eg, autoimmune, malignant, foreign-body) etiologies may mimic bacterial cellulitis. Defining the etiology of the cellulitis allows prompt and effective treatment.

Bacterial infections of the orbit or periorbital soft tissues originate from 3 primary sources:

- direct spread from adjacent sinusitis, dacryocystitis, dacryoadenitis, or an odontogenic infection
- direct inoculation after trauma or skin infection
- hematologic spread from a distant focus (eg, otitis media, pneumonia, endocarditis)

Preseptal cellulitis

Preseptal cellulitis involves structures anterior to the orbital septum. Eyelid edema, erythema, and inflammation may be severe, but the globe and deep orbital tissues remain uninvolved

Table 4-1 Differential Diagnosis of Major Orbital Inflammations

Infectious (identify as preseptal or orbital cellulitis)
Bacterial (identify the source)
Direct inoculation (trauma, surgery)
Spread from adjacent tissue (sinusitis, dacryocystitis, dacryoadenitis)
Spread from distant focus (bacteremia, pneumonia)
Opportunistic infection (necrotizing fasciitis, tuberculosis)
Fungal
Mucormycosis
Aspergillosis
Parasitic
Echinococcosis
Cysticercosis
Autoimmune
Thyroid eye disease (TED)
Immunoglobulin G4–related disease (IgG4-RD)
Vasculitic
Giant cell arteritis
Granulomatosis with polyangiitis
Polyarteritis nodosa
Vasculitis associated with connective tissue disorders
Granulomatous
Sarcoidosis
Foreign body
Nonspecific orbital inflammation (NSOI) (diagnosis of exclusion)

(Fig 4-1). Therefore, pupillary reaction, vision, ocular motility, and globe position are not disturbed. Furthermore, pain on eye movement and chemosis are typically absent.

Although preseptal cellulitis in adults usually arises from penetrating cutaneous trauma or dacryocystitis, in children, it commonly arises from underlying sinusitis. Most pediatric cases are now caused by gram-positive cocci, but *Haemophilus influenzae* type B should still be considered, especially in nonimmunized children.

Treatment Antibiotic therapy and workup should begin as promptly as possible, particularly in children. If eyelid swelling precludes motility evaluation and, thus, the ability to exclude orbital cellulitis, workup should include computed tomography (CT) imaging of the orbit and sinuses. An appropriate antibiotic regimen may be developed in collaboration with the primary care physician or an infectious disease specialist.

In children with a reliable examination and follow-up plan, oral antibiotics (eg, cephalexin for an anterior etiology; amoxicillin clavulanate for a sinusitis-associated infection), frequent warm compresses, and nasal decongestants (eg, oxymetazoline nasal spray) for associated sinusitis typically improve the infection. For infants, children with an unreliable examination or follow-up plan, or for infections that progress on oral antibiotics, hospital admission and intravenous (IV) antibiotics (eg, ceftriaxone, vancomycin) may be considered.

In teenagers and adults, preseptal cellulitis usually arises from a superficial source and responds quickly to appropriate oral antibiotics (eg, ampicillin-sulbactam, trimethoprim-sulfamethoxazole [TMP-SMX], doxycycline, clindamycin) and warm compresses. Initial antibiotic selection depends on the history, clinical findings, and initial laboratory studies.

Figure 4-1 A patient with preseptal cellulitis of the right upper eyelid with formation of a localized abscess. The eye remains quiet, with no chemosis or proptosis. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Prompt culture and sensitivity studies allow for revision of antibiotic therapy in unresponsive cases.

In older adults or patients with immunosuppression, infections behave differently and may not produce typical signs, such as erythema, calor, or fever. Response to antibiotics in patients in this age group may also be delayed, and surgical intervention to excise devitalized tissue may be necessary to clear an infection. If the patient does not respond to oral antibiotics within 48 hours, or the infection progresses to orbital involvement, imaging studies and hospital admission for IV antibiotics may be warranted to rule out underlying sinusitis, especially in the absence of a direct inoculation site. Coordinating management with the primary care, infectious disease, and/or otolaryngology teams is important.

In any patient cohort, preseptal cellulitis that progresses to a localized abscess may require surgery (see Fig 4-1). Incision and drainage directly over the abscess typically improve the infection, and dissection of the upper eyelid should preserve the orbital septum to avoid contaminating the orbital soft tissues and to prevent injury to the underlying levator aponeurosis.

In patients with preseptal cellulitis that results from trauma, *Staphylococcus aureus* represents the most common pathogen. The infection usually responds rapidly to a penicillin used against penicillinase-resistant organisms, such as methicillin or ampicillin-sulbactam. However, *methicillin-resistant S aureus (MRSA),* previously recognized as a cause of severe nosocomial infections, is now increasingly encountered in the community setting.

Community-acquired (CA)-MRSA infections tend to present as a fluctuant abscess with surrounding cellulitis. Eyebrow abscesses have a particularly high rate of CA-MRSA–positive cultures. The pain associated with the lesion is often out of proportion to its appearance. Classically, CA-MRSA has been susceptible to a wider range of antibiotics (including TMP-SMX, rifampin, or clindamycin), compared with susceptibility of hospital-associated (HA)-MRSA. Over the past decade, however, antibiotic-resistant CA-MRSA strains have migrated into the health care setting, and the genetic differences and outcomes between CA-MRSA and HA-MRSA infections have increasingly overlapped. Both types of MRSA may result in acute morbidity and long-term disability. MRSA has also been associated with necrotizing fasciitis, orbital cellulitis, endogenous endophthalmitis, panophthalmitis, and cavernous sinus thrombosis.

Orbital cellulitis

Orbital cellulitis involves structures posterior to the orbital septum and occurs as a secondary extension of acute or chronic bacterial sinusitis in the majority of cases (Table 4-2). Clinical findings include fever, leukocytosis (75% of cases), erythema, proptosis, chemosis, ptosis, and restriction of and pain with ocular movement (Fig 4-2A, B). Decreased vision, impaired color vision, restricted visual fields, and pupillary abnormalities suggest optic neuropathy that demands immediate investigation and aggressive management. Delay in treatment may result in blindness, cavernous sinus thrombosis, cranial neuropathy, meningitis, or death. Treatment may require a multidisciplinary approach.

Orbital findings indicate that imaging is needed to identify sinusitis, which may require treatment from an otolaryngologist. Antibiotic therapy in adults should provide broad-spectrum coverage because such infections usually involve multiple organisms that may include gram-positive cocci, such as *H influenzae, Moraxella catarrhalis,* and anaerobes. Although nasal decongestants promote drainage of the infected sinus, sinus surgery is often required, especially if orbital findings progress during IV antibiotic therapy. In contrast, orbital cellulitis in children is more often caused by a single gram-positive organism and is less likely to require surgical sinus drainage.

Progressive proptosis, globe displacement, or lack of response to appropriate antibiotic therapy suggests abscess formation, which can be identified on orbital CT imaging with contrast or MRI and guides the approach for surgical intervention. Abscesses usually localize in the subperiosteal space (Fig 4-2C, D), adjacent to the infected sinus, but may extend through the periosteum into the orbital soft tissues.

However, not all subperiosteal abscesses (SPAs) require surgical drainage. Isolated medial or inferior SPAs in children younger than 9 years with underlying isolated ethmoid sinusitis, intact vision, and only moderate proptosis typically respond to medical therapy. Management may consist of careful observation *unless any of the following criteria is present:*

- patient age is 9 years or older
- presence of frontal sinusitis
- nonmedial SPA location (see Fig 4-2C, D)
- large SPA
- suspicion of anaerobic infection (eg, presence of gas in abscess on CT)
- recurrence of SPA after prior drainage
- evidence of chronic sinusitis (eg, nasal polyps)
- acute optic nerve or retinal compromise
- infection of dental origin (anaerobic infection more likely)

In patients with these criteria or with infections refractory to medical therapy, surgical drainage coupled with appropriate antibiotic therapy typically leads to clinical improvement within 24–48 hours. Sinusitis may improve with concomitant sinus surgery. The refractory nature of orbital abscesses in adolescents and adults may relate to the frequent involvement of multiple and drug-resistant pathogens, particularly anaerobic organisms.

Treatment with corticosteroids may speed resolution of inflammation and decrease the length of a patient's hospital stay, although the timing and dosage remain controversial. Their use should be balanced by the risk of masking infection progression.

Table 4-2 Causes of Orbital Cellulitis

Extension from periorbital structures
Paranasal sinuses (sinusitis)
Face and eyelids (infection of)
Lacrimal sac (dacryocystitis)
Dental (odontogenic infection)
Exogenous causes
Trauma (rule out foreign bodies)
Surgery (after any orbital or periorbital surgery)
Endogenous causes
Bacteremia with septic embolization
Intraorbital causes
Endophthalmitis
Dacryoadenitis

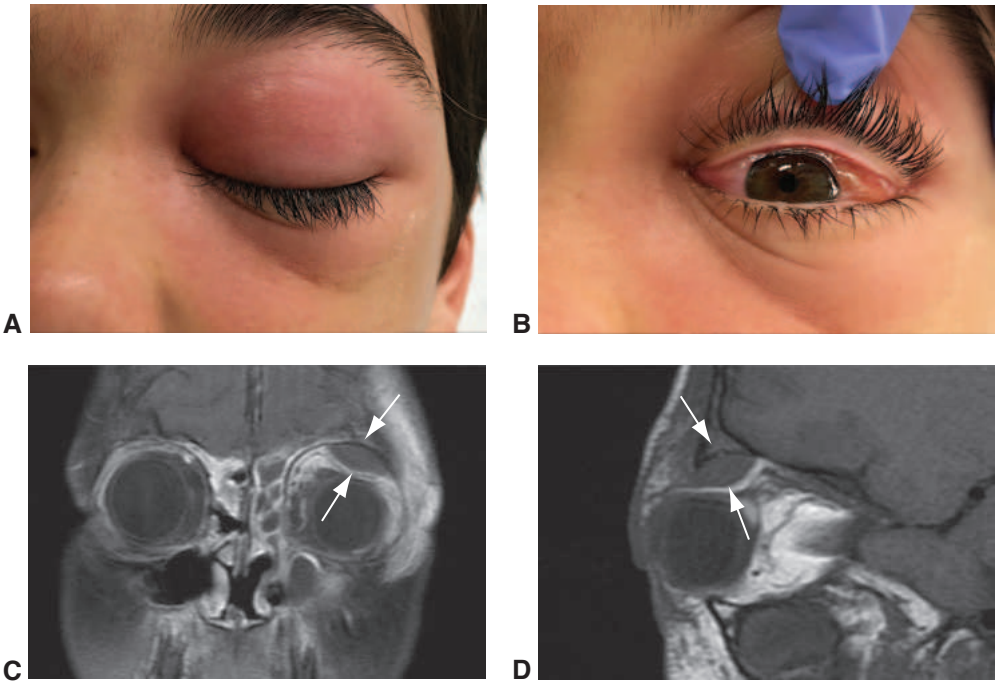

Figure 4-2 Left-side orbital cellulitis. **A,** Marked periocular erythema is present, as is upper-eyelid ptosis. **B,** Chemosis is present upon elevation of the eyelid. **C** and **D,** T1-weighted magnetic resonance imaging (MRI) with gadolinium contrast reveals a superior subperiosteal abscess *(arrows).* *(Courtesy of Cat N. Burkat, MD.)*

Because orbital cellulitis and abscesses respond to therapy in most patients, orbital infections rarely spread posteriorly to the cavernous sinus. Cavernous sinus thrombosis is often heralded by the following signs:

- rapid progression of proptosis
- development of ipsilateral ophthalmoplegia
- onset of anesthesia in both the first and second divisions of the trigeminal nerve

In rare instances, contralateral ophthalmoplegia, meningitis, or a brain abscess may develop.

Lumbar puncture may reveal acute inflammatory cells and the causative organism on stain and culture tests. Contrast-enhanced magnetic resonance imaging (MRI) may help confirm the diagnosis.

Orbital cellulitis caused by MRSA may occur without antecedent respiratory illness or trauma and without adjacent paranasal sinus disease on imaging. MRSA orbital cellulitis may require surgical intervention more often than typical orbital cellulitis, and it may also lead to significant decrease of visual acuity more often, especially in cases in which referral for surgical intervention has been delayed. Because of the potentially aggressive nature of this pathogen, successful management demands a high degree of clinical suspicion and prompt medical and surgical intervention. In addition, consultation with specialists in infectious diseases may be warranted.

Orbital cellulitis following blowout fractures generally occurs in patients with underlying sinus disease or a medial wall fracture. Prophylactic antibiotics can be considered in these cases.

Odontogenic infections may spread through the sinuses to cause orbital cellulitis. These infections account for 2%–5% of all orbital cellulitis cases and can arise from any tooth, although most develop from maxillary premolar teeth. These infections are typically polymicrobial and often consist of gram-positive aerobes and anaerobes.

Garcia GH, Harris GJ. Criteria for nonsurgical management of subperiosteal abscess of the orbit: analysis of outcomes 1988–1998. *Ophthalmology.* 2000;107(8):1454–1456, discussion 1458.

Necrotizing Fasciitis

Necrotizing fasciitis is a severe, potentially vision-threatening or life-threatening bacterial infection involving the subcutaneous soft tissues, particularly the superficial and deep fasciae. A variety of organisms may cause this disorder, including aerobic and anaerobic, gram-positive and gram-negative bacteria, but the organism most commonly responsible is group A β-hemolytic *Streptococcus*.

This infection develops rapidly and requires immediate attention because it is potentially fatal. Although most affected patients are immunocompromised, it may occur in immunocompetent patients as well. See Key Points 4-1.

KEY POINTS 4-1

Necrotizing fasciitis The following list highlights the essential points for the ophthalmologist to remember about necrotizing fasciitis.

- The initial clinical presentation is similar to that of orbital or preseptal cellulitis, with swelling, erythema, and pain, but it may be accompanied by a shocklike syndrome.
- Because necrotizing fasciitis tends to track along avascular tissue planes, an early sign may be anesthesia over the affected area due to involvement of deep cutaneous nerves.
- Reports of disproportionate pain may suggest the presence of necrotizing fasciitis, as do skin-color changes that progress from rose to blue-gray, with bullae formation and frank cutaneous necrosis.

- The course is usually rapid, with the patient requiring treatment in an intensive care unit.
- Patients may experience rapid deterioration that culminates in hypotension, renal failure, and adult respiratory distress syndrome.

Treatment may include early surgical debridement along with IV antibiotics (Fig 4-3). If the involved pathogen is unknown, broad-spectrum coverage for gram-positive and gram-negative as well as anaerobic organisms is indicated. Clindamycin is effective in treating infections due to most causative organisms and acts against the toxins produced by group A β-hemolytic *Streptococcus*. To limit the inflammatory damage associated with the toxins, adjunctive corticosteroid therapy after the start of antibiotic therapy has been advocated. Some cases of necrotizing fasciitis are limited to the eyelids, with clearly defined margins and without signs of toxic shock; these cases can be cautiously followed with systemic antibiotic therapy alone or with little or no surgical debridement.

Although clinical series from all body sites report up to a 30% mortality rate, usually due to toxic shock syndrome, this occurs less commonly in patients who have infection in the periocular region.

Perry, MD, and Catherine J. Hwang, MD.)*

Mycobacterial Infection

Although it is largely endemic to the developing world, tuberculosis may occur in the developed world as well, most often in individuals with HIV infection or in association with inner-city poverty. Orbital tuberculosis usually results after hematogenous spread from an often-subclinical pulmonary focus, but it may also arise from adjacent tuberculous sinusitis.

Patients may present with proptosis, motility dysfunction, bone destruction, and chronic draining fistulas. Most orbital cases are unilateral and occur in children, in whom the infection may masquerade as an orbital malignancy. Pathologic specimens may not reveal acid-fast bacilli, but usually show caseating necrosis, epithelioid cells, and Langerhans giant cells. Skin testing and fine-needle aspiration biopsy with culture performed early in the course of the disease may help establish the diagnosis. Antituberculous therapy is usually curative.

Nontuberculous (atypical) mycobacteria may also infect the periocular tissues. Predisposing factors include immunosuppression, nasolacrimal duct obstruction, trauma, and a history of recent periocular surgery. Postoperative infections occur most commonly after lacrimal surgery but can occur after blepharoplasty as well (Fig 4-4). The causative organisms, which are identified in less than one-third of reported cases, are typically *Mycobacterium chelonae* or *Mycobacterium fortuitum.* Treatment consists of periocular debridement and systemic antituberculous antibiotics.

Mucormycosis

Mucormycosis is the most common and the most virulent fungal disease involving the orbit. The specific fungal genus involved is usually *Mucor* or *Rhizopus.* These fungi, which belong to the class Zygomycetes, almost always extend into the orbit from an adjacent sinus or the nasal cavity. The fungi invade blood vessel walls, producing thrombosing vasculitis. The resultant tissue necrosis promotes further fungal invasion.

Patients commonly present with proptosis and an orbital apex syndrome (internal and external ophthalmoplegia, ptosis, decreased corneal sensation, and decreased vision). Ascending infection may result in cavernous sinus thrombosis (Fig 4-5). Because of the thrombosing vasculitis, the infection may not produce significant orbital inflammation, so an unusually white and quiet eye should prompt concern for orbital ischemia.

Predisposing factors include systemic disease with associated metabolic acidosis, diabetes mellitus, malignancies, immunosuppression, and treatment with antimetabolites or

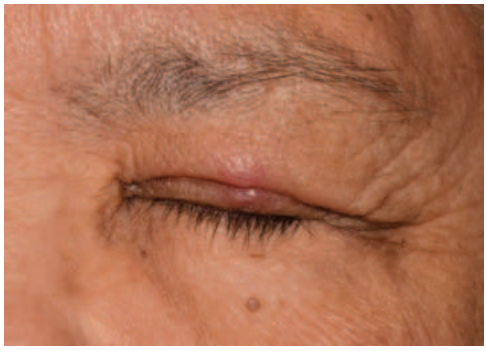

Figure 4-4 A patient presents with delayed infection of the left upper eyelid by nontuberculous (atypical) mycobacteria after blepharoplasty. *(Courtesy of Bobby S. Korn, MD, PhD.)*

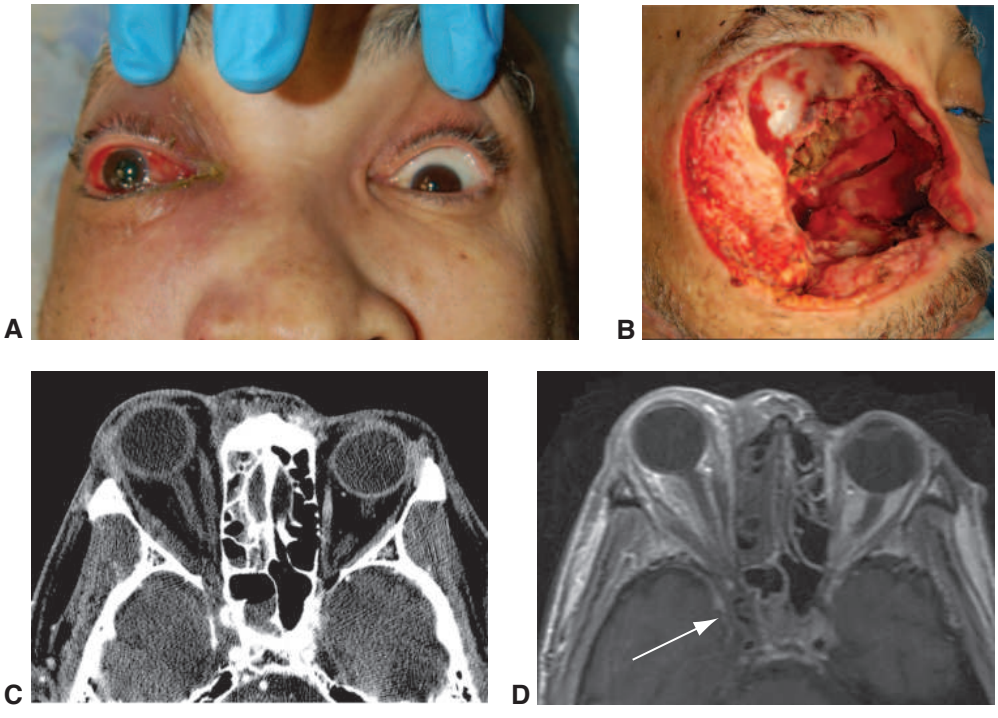

Figure 4-5 Right-sided sino-orbital invasive fungal sinusitis in a patient with diabetic ketoacidosis. **A,** Patient demonstrates complete right upper-eyelid ptosis and ophthalmoplegia. **B,** Wide surgical debridement consisting of orbital exenteration and sinus surgery was lifesaving. steroids. Biopsy of the necrotic-appearing tissues in the nasopharynx, involved sinus, or orbit confirms the diagnosis and shows nonseptate, large branching hyphae that stain with hematoxylin-eosin, unlike most fungi (see the discussion of mucormycosis in BCSC Section 5, *Neuro-Ophthalmology*).

Treatment should include a multidisciplinary team to address any underlying predisposing disease, perform wide surgical debridement, and administer antifungal therapy. Diabetic ketoacidosis, in particular, requires prompt correction; this condition produces more free serum iron, thought to be central to fungal pathogenesis. Antifungal therapy may consist of IV or liposomal amphotericin B; posaconazole or voriconazole may be used in patients who cannot tolerate the adverse effects of amphotericin. In addition, retrobulbar injection of amphotericin B may be considered. Adjunctive treatments include hyperbaric oxygen therapy. Despite aggressive surgical debridement, including exenteration, the prognosis for survival remains poor and often depends on whether the underlying systemic predisposing disease is immediately treatable.

Ashraf DC, Idowu OO, Hirabayashi KE, et al. Outcomes of a modified treatment ladder algorithm using retrobulbar Amphotericin B for invasive fungal rhino-orbital sinusitis. *Am J Ophthalmol.* 2022;237:299–309.

Aspergillosis

Fungi in the *Aspergillus* genus can affect the orbit in several distinct clinical entities. *Acute invasive aspergillosis* is a fungal disease characterized by fulminant sinus infection with secondary orbital invasion. Patients present with severe periorbital pain, decreased vision, and proptosis. Diagnosis is confirmed by biopsy. Grocott-Gomori methenamine–silver nitrate stain shows septate branching hyphae of uniform width (see the discussion of aspergillosis in BCSC Section 5, *Neuro-Ophthalmology*). Therapy consists of aggressive surgical excision of all infected tissues and administration of antifungal agents, including polyenes (amphotericin B, liposomal amphotericin B), azoles (eg, itraconazole, voriconazole), echinocandins (caspofungin), and pyrimidine analogues (flucytosine), or a combination thereof.

Chronic necrotizing aspergillosis is an indolent infection that results in slow destruction of the sinuses and adjacent structures. Although the prognosis is much better than that for acute fulminant disease, intraorbital and intracranial extension can still occur and result in significant morbidity.

Chronic, localized noninvasive aspergillosis also involves the sinuses and occurs in immunocompetent patients who may not have a history of atopic disease. Often, there is a history of chronic sinusitis, and the proliferation of fungal organisms results in a tightly packed fungus ball. This type of aspergillosis is characterized by a lack of inflammation and/or bone erosion.

Allergic aspergillosis sinusitis occurs in immunocompetent patients with nasal polyposis and chronic sinusitis. Patients may have peripheral eosinophilia; elevated total immunoglobulin E (IgE), fungus-specific IgE, and immunoglobulin G (IgG) levels; or positive skin test results for fungal antigens. CT imaging reveals mottled areas of increased attenuation on nonenhanced images; these correspond to thick allergic mucin within the sinus. Bone erosion and remodeling, while often present, do not signify tissue invasion. MRI may be more specific, as it shows signal void areas on T2-weighted scans. Sinus biopsy reveals thick, peanut butter–like or green mucus, and histologic examination shows numerous eosinophils, eosinophil degradation products, and extramucosal fungal hyphae. Treatment consists of endoscopic sinus debridement as well as systemic and topical corticosteroids. Up to 17% of patients with allergic fungal sinusitis initially present with orbital signs.

Chang WJ, Tse DT, Bressler KL, Casiano RR, Rosa RH, Johnson TE. Diagnosis and management of allergic fungal sinusitis with orbital involvement. *Ophthalmic Plast Reconstr Surg.* 2000;16(1):72–74.

Parasitic Diseases

Parasitic diseases of the orbit generally occur in developing countries. *Trichinosis*, caused by ingestion of the nematode *Trichinella spiralis*, may produce inflammation of the eyelids and extraocular muscles as a result of larval migration. *Echinococcosis*, caused by the dog tapeworm *Echinococcus granulosus*, may manifest as a hydatid cyst within the orbit (Fig 4-6). Rupture of the cyst, which contains tapeworm larvae, may cause progressive inflammation and a severe immune response. *Taenia solium,* the pork tapeworm, may also encyst within the orbit and progressively enlarge to cause a condition known as *cysticercosis.*

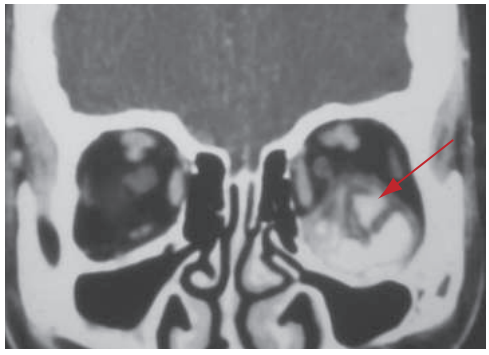

Figure 4-6 Coronal CT scan demonstrates a hydatid cyst of the left inferior rectus muscle *(arrow)*. *(Courtesy of Don O. Kikkawa, MD.)*

Noninfectious Inflammation

Thyroid Eye Disease

Thyroid eye disease (TED; also known as *Graves ophthalmopathy, thyroid-associated orbitopathy,* and other terms) represents an autoimmune inflammatory disorder with characteristic clinical signs (Figs 4-7 to 4-10). Originally described as part of the triad of Graves disease (orbital signs, hyperthyroidism, and pretibial myxedema), TED most often occurs in individuals with Graves hyperthyroidism. However, TED may also occur with Hashimoto thyroiditis (immune-induced hypothyroidism) or in the absence of thyroid dysfunction. The course of the eye disease does not necessarily parallel the activity of the thyroid gland or the treatment of thyroid abnormalities. See Key Points 4-2.

KEY POINTS 4-2

Thyroid eye disease (TED) The following list highlights the essential points for the ophthalmologist to remember about TED.

- Eyelid retraction is the most common clinical feature of TED (and TED is the most common cause of eyelid retraction).
- TED is the most common cause of unilateral or bilateral proptosis.
- TED may be markedly asymmetric.
- TED is associated with hyperthyroidism in 90% of patients, but 6% of patients may be euthyroid.
- Severity of TED usually does not parallel serum levels of triiodothyronine (T_3) or free thyroxine (T_4).
- TED is between 6 and 7 times more common in women than men.
- Smoking is associated with increased risk and severity of TED.
- Urgent intervention may be required for optic neuropathy or severe proptosis with corneal decompensation.
- If surgery is needed, the usual order is orbital decompression, followed by strabismus surgery, followed by eyelid retraction repair (see Chapter 7 in this volume).
- Radiotherapy may prevent optic neuropathy and may improve some aspects of TED, but its role remains controversial.

Diagnosis

The diagnosis of TED is made when 2 of the following 3 signs are present:

1. Concurrent or recently treated immune-related thyroid dysfunction:
    a. Graves hyperthyroidism
    b. Hashimoto thyroiditis
    c. Presence of circulating thyroid antibodies without a coexisting dysthyroid state (partial consideration given): thyroid-stimulating hormone–receptor (TSH-R) antibodies, thyroid-binding inhibitory immunoglobulins, thyroid-stimulating immunoglobulins (TSI), antimicrosomal antibodies
2. Typical ocular signs:
    a. Chemosis and/or caruncular edema (see Fig 4-7)
    b. Restrictive strabismus in a typical pattern (see Fig 4-8)
    c. Unilateral or bilateral eyelid retraction with typical lateral flare (see Fig 4-9)
    d. Unilateral or bilateral proptosis (see Fig 4-10)
    e. Compressive optic neuropathy
    f. Fluctuating eyelid edema and/or erythema
3. Radiographic evidence of TED: unilateral or bilateral fusiform enlargement of any of the rectus muscles (sparing the tendon) and/or the levator muscle complex (Fig 4-11).

Serologic testing of serum thyroid-stimulating hormone (TSH), triiodothyronine (T_3), and free thyroxine (T_4) levels is well established in the diagnosis of thyroid disease. However, the usefulness of these tests in monitoring TED treatment and progression is unclear because the systemic disease and the eye disease are discordant.

Tests of autoimmune function may be helpful in evaluating disease activity and severity. TSH receptor (TSH-R) antibody testing can be performed by measuring all immunoglobulins that target the TSH-R (eg, the thyrotropin-binding inhibitory immunoglobulin [TBII] test) or by measuring only the stimulating antibodies (eg, the thyroid-stimulating immunoglobulin [TSI] assay).

These tests may help identify the cause of the thyroid disease and patients at high risk for TED, although results should be interpreted with caution because the diagnosis of TED is based mainly on clinical findings. Thyroid peroxidase antibody (TPO) testing has replaced antimicrosomal antibody testing, but the presence of this antibody does not correlate with TED activity or severity or TSI levels. Similarly, thyroglobulin antibody levels do not correlate with TED. While insulin-like growth factor I (IGF-I) antibody levels may represent a future area of serologic testing for TED, no current recommendations exist.

Pathogenesis

Orbital fibroblasts, through the expression of characteristic surface receptors, gangliosides, and proinflammatory genes, play an active role in modulating the inflammatory process. Unlike fibroblasts from other body sites, orbital fibroblasts express CD40 receptors, which are generally found on B cells. When engaged by T-cell–bound CD154, several fibroblast proinflammatory cytokines are upregulated, including interleukin 6 (IL-6) and interleukin 8 (IL-8), as well as prostaglandin E2, increasing synthesis of hyaluronan and glycosaminoglycan (GAG). This upregulation of orbital fibroblast GAG synthesis represents an essential aspect of the pathology of TED, and it occurs at a rate 100 times that of abdominal fibroblasts from the same patient. Therapeutic levels of corticosteroids dampen the upregulation cascade.

Orbital fibroblasts, which are embryologically derived from the neural crest lineage, possess developmental plasticity. A subpopulation of orbital fibroblasts appears capable of

undergoing adipocyte differentiation; this contributes to the expansion of orbital fat that predominates in some patients.

Insulin-like growth factor I receptor (IGF-1R) is a tyrosine kinase receptor that contains 2 alpha subunits and 2 beta subunits linked by 2 disulfide bonds. Research has demonstrated that overexpression of the IGF-1R expressed on the surface of orbital fibroblasts, B cells, and T cells in patients with Graves disease may stimulate orbital fibroblasts to secrete GAGs, cytokines, and chemoattractants. These latter signaling families may contribute to orbital inflammation and congestion.

Kazim M, Goldberg RA, Smith TJ. Insights into the pathogenesis of thyroid-associated orbitopathy: evolving rationale for therapy. *Arch Ophthalmol.* 2002;120(3):380–386.

Epidemiology

A 1996 epidemiologic study of White patients with TED in the United States determined that the overall age-adjusted incidence per 100,000 people per year was 16 cases for women and 3 cases for men. The peak incidences occurred in the age groups 40–44 years and 60–64 years in women and 45–49 years and 65–69 years in men. Development of TED is up to 7 times more likely for smokers than nonsmokers.

Clinical features

Among patients with TED, about 90% have Graves hyperthyroidism, 6% are euthyroid, 3% have Hashimoto thyroiditis, and 1% have primary hypothyroidism. A close temporal relationship exists between the development of hyperthyroidism and the development of TED: in about 20% of patients, the diagnoses are made at the same time, and in about 60% of patients, the eye disease occurs within 1 year of onset of the thyroid disease. For patients who have no history of abnormal thyroid function at the time TED is diagnosed, the risk for development of thyroid disease is about 25% within 1 year and 50% within 5 years. Although hyperthyroidism is present or will develop in most patients with TED, only about 30% of patients with autoimmune hyperthyroidism will develop TED.

Pretibial myxedema accompanies TED in about 4% of patients. Acropachy (soft-tissue swelling and periosteal changes affecting the distal extremities, principally fingers and toes) accompanies TED in about 1% of patients. Both are associated with a poor orbitopathy prognosis. Myasthenia gravis occurs in fewer than 1% of patients and should be considered when ptosis or exotropia accompanies TED.

The most frequent presenting ocular symptoms and signs of TED are:

- upper eyelid retraction (unilateral or bilateral)
- eyelid lag with downgaze (unilateral or bilateral, 50% of patients; see Fig 4-10)
- dull, deep orbital pain or discomfort (30% of patients).

Dysthyroid optic neuropathy is present in less than 2% of eyes at the time of diagnosis of TED. Upper eyelid retraction occurs in more than 90% of patients during their clinical course (see Fig 4-9); exophthalmos (unilateral or bilateral) in 60%; restrictive extraocular myopathy in 40%; and optic neuropathy (unilateral or bilateral) in 5%. Only 5% of patients develop the complete constellation of these 4 classic findings and hyperthyroidism. Some degree of diplopia is reported by about 17% of patients, lacrimation or photophobia by 15%–20% of patients, and blurred vision by 7% of patients.

Bartley GB, Fatourechi V, Kadrmas EF, et al. Clinical features of Graves' ophthalmopathy in an incidence cohort. *Am J Ophthalmol.* 1996;121(3):284–290.

Treatment and prognosis

TED is a self-limiting disease that on average lasts 1 year in nonsmokers and between 2 and 3 years in smokers. After the active disease plateaus, a chronic phase that follows Rundle's curve ensues (Fig 4-12). Reactivation of inflammation occurs in 5%–10% of patients over their lifetimes.

Although several clinical scoring systems to guide TED evaluation and treatment exist, including NO SPECS (No physical signs or symptoms, Only signs, Soft-tissue involvement, Proptosis, Extraocular muscle signs, Corneal involvement, Sight loss), CAS (Clinical Activity Score), and VISA (Vision, Inflammation, Strabismus, Appearance), no system prevails. The CAS and VISA systems each assign points for various findings; the CAS adds extra parameters for follow-up visits and the VISA uses the same scale for both initial and follow-up visits. Treatment of patients with TED follows a stepwise and graded approach based on symptoms, clinical examination, and ancillary testing (Tables 4-3, 4-4).

Most patients with TED in the active phase require only smoking cessation and supportive care, including use of topical ocular lubricants. The following may also be helpful:

- topical cyclosporine, which may reduce ocular surface irritation
- a reduced-salt diet and sleeping with the head of the bed elevated, which may limit orbital edema
- wearing wraparound sunglasses, which may relieve exposure and dry eye symptoms
- temporary prism glasses, which may help maintain binocular fusion

In addition, selenium supplementation may improve the course of disease, especially in patients heralding from selenium-deficient regions. Neurotoxins can temporarily improve upper eyelid retraction by weakening the eyelid elevators. Neurotoxins can also be used to treat restrictive strabismus by weakening affected extraocular muscle(s).

Severe orbital inflammation may mandate early intervention to improve corneal exposure, globe subluxation, or optic neuropathy. Therapies generally attempt to decrease

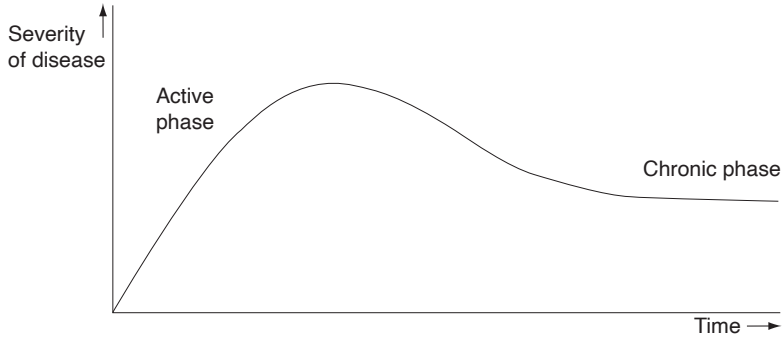

Figure 4-12 Rundle's curve as applied to the typical course of TED.

Table 4-3 VISA and CAS Inflammatory Scoring Systems

VISA: Presence of each sign/symptom receives 1–2 points as noted (maximum score of 10). Patients with sum scores <4/10 are managed conservatively, while patients with scores >5/10 or with evidence of inflammatory progression are managed more aggressively.
Swelling of caruncle (1 point)
Conjunctival chemosis (2 points)
Conjunctival erythema (1 point)
Eyelid erythema (1 point)
Eyelid swelling (2 points)
Retrobulbar ache (2 points)
Diurnal variation (1 point)
CAS: Presence of each sign/symptom receives 1 point. A sum score of >3/7 at first examination or >4/10 at subsequent examinations defines active ophthalmopathy.
Initial examination (maximum score of 7 points)
Ocular or retrobulbar pain
Pain with eye movement
Eyelid erythema
Eyelid swelling
Conjunctival chemosis
Conjunctival erythema
Swelling/erythema of caruncle
Subsequent examination (maximum score of 10 points, combining initial findings with parameters below)
>2-mm increase in proptosis
Impaired duction >8° in any 1 direction
>1-line decrease in Snellen visual acuity chart

orbital congestion and inflammation (eg, glucocorticoids, targeted therapy, radiotherapy), mechanically protect the cornea (eg, tarsorrhaphy), expand the orbital volume (eg, bony orbital decompression), or reduce orbital soft tissue volume (eg, orbital fat decompression).

Establishing the euthyroid state represents a mainstay of therapy. Hyperthyroidism is most commonly treated with antithyroid drugs and sometimes with radioactive iodine (RAI). In some patients, RAI treatment may worsen TED, presumably because the TSH-R antigen release incites an enhanced immune response. In addition, hypothyroidism occurring after RAI treatment may exacerbate TED via stimulation of TSH-R. Exacerbation of TED after RAI treatment may occur more commonly in hyperthyroid patients with severe, active TED; those with elevated T_3 levels; and smokers. Oral glucocorticoid treatment may limit TED progression in patients with risk factors such as these, but it is not indicated for patients without preexisting TED and without risk factors. Another strategy, termed *block-and-replace therapy* (eg, with iodine 131, methimazole, and thyroxine) reduces exacerbation of eye findings by limiting posttreatment TSH spikes. Another option, usually reserved for patients whose disease is refractory to RAI or those with severe TED, involves thyroidectomy, which creates hypothyroidism without extended antigen release.

Table 4-4 General Management of Thyroid Eye Disease

Mild disease
Observation
Patient education and lifestyle changes
Smoking cessation
Salt restriction
Elevation of head of bed
Use of sunglasses
Ocular surface lubrication
Establishment of a euthyroid state
Oral selenium
Moderate disease
Topical cyclosporine
Eyelid taping at night
Moisture goggles or chambers
Prism glasses or selective ocular patching
Moderate-dose oral corticosteroid therapy or steroid-sparing immunomodulators
Surgical orbital decompression (followed by strabismus surgery and/or eyelid surgery), if indicated
Severe disease
High-dose intravenous corticosteroid therapy or steroid-sparing immunomodulators
Surgical orbital decompression (followed by strabismus surgery and/or eyelid surgery)
Periocular radiotherapy
Refractory disease
Steroid-sparing immunomodulators
Surgical orbital decompression (followed by strabismus surgery and/or eyelid surgery)

While oral glucocorticoids were commonly used at high dosage in the past, now the usual starting dose is 1 mg/kg prednisone until a clinical response is apparent. The dose is then reduced as rapidly as possible, based on the clinical response of optic nerve function. Although effective, high-dose glucocorticoids are associated with an extensive list of potential systemic adverse effects, limiting their long-term use. Patients with active TED may benefit from weekly IV methylprednisolone therapy for 6–12 weeks. Hepatic function should be checked before administration and monitored throughout treatment due to potentially fatal hepatotoxicity, which can be seen with high cumulative doses. Patients demonstrating features of compressive optic neuropathy may benefit from IV glucocorticoid bridge treatment prior to surgical decompression.

Some reports suggest that treatment with fractionated orbital radiotherapy improves compressive optic neuropathy and other signs of TED in some patients, possibly by inducing terminal differentiation of fibroblasts and killing tissue-bound monocytes, which play an important role in antigen presentation. Recent evidence has suggested that it may provide a protective effect against the development of optic neuropathy. Given the biologic effects of radiation, it is likely more useful in the active phase of the disease. Although radiation has been used for decades, a wealth of data both support and refute its use, with and without the use of glucocorticoids, for many signs and symptoms of TED. Radiation therapy carries a rare risk of exacerbating diabetic retinopathy and other ischemic retinopathies.

Treatment with rituximab may affect the clinical course of TED by blocking the CD20 receptor on B lymphocytes; however, it does not appear to target the central mechanisms

of the disease, and most clinicians currently use this only as a second-line therapy in select cases. Tocilizumab, a monoclonal IL-6 antibody, may reduce inflammatory signs and even TSI via an upstream effect on the inflammatory cycle. A variety of other anti-inflammatory, antimetabolite, and biologic agents have been employed with limited success.

The United States Food and Drug Administration (FDA) has approved teprotumumab, a human monoclonal antibody inhibitor of IGF-IR, to reduce exophthalmos and the CAS in patients with TED. Teprotumumab may specifically target the autoimmune process underlying TED by binding to the extracellular alpha subunit of the IGF-1R that is overexpressed on the surface of orbital fibroblasts; this then decreases the signaling cascade by reducing secretion of GAGs and cytokines. Teprotumumab appears well tolerated, although hyperglycemia, hearing loss, and exacerbation of inflammatory bowel disease may occur. Reliable contraception is essential during the use of teprotumumab due to its potential teratogenicity. Recurrence of inflammation after cessation of treatment, durability of exophthalmos reduction, and the very high cost of the medication can be limiting factors.

Orbital decompression surgery is effective in treating patients with compressive optic neuropathy and inactive TED with disfiguring proptosis or severe exposure keratopathy. In the postinflammatory phase of the condition, the first stage of surgical rehabilitation is decompression to address disfiguring or symptomatic proptosis. Preoperative CT imaging details the relative contributions of extraocular muscle enlargement and fat expansion to the proptosis (see Fig 4-11). Patients with more enlargement of the orbital fat compartment (type I orbitopathy) may benefit from more fatty decompression, whereas patients with more extraocular muscle enlargement (type II orbitopathy) may benefit from more bony decompression. Fat and bone removal can be combined, graded, and tailored to achieve different amounts of proptosis reduction and minimize adverse effects such as diplopia, hypoglobus, and sinusitis. See Chapter 7 for further discussion of orbital decompression.

Because decompression may produce or worsen diplopia, it should precede strabismus surgery, which may help restore single vision in patients with intractable diplopia in primary gaze or in the reading position. Prisms represent another option for patients with relatively comitant strabismus and those with a small deviation after strabismus surgery.

Surgery to recess the rectus muscles can change eyelid position, so strabismus surgery typically precedes eyelid repositioning surgery. Levator and/or Müller muscle recession improves upper eyelid retraction to decrease corneal exposure and help improve appearance. The lower eyelids can be repositioned as well, typically by recessing the eyelid retractors, with or without a spacer graft or during a midface-lift. Finally, the last stage of surgery involves addressing periocular soft tissue changes. These techniques often address redundant skin and fatty tissues in addition to independent periocular aging changes.

Elective orbital decompression, strabismus surgery, and eyelid retraction repair are usually not considered until a euthyroid state with stable ophthalmic signs has been achieved and maintained for at least 6 months.

Fortunately, treatment usually mitigates vision loss from optic neuropathy, and prism glasses typically treat persistent diplopia. Subjectively, however, more than 50% of patients believe that their eyes look abnormal, and 38% of patients are dissatisfied with the

appearance of their eyes. Thus, although significant long-term functional impairment from TED remains uncommon, the disease leaves lasting psychological and aesthetic sequelae.

Vasculitis

The vasculitides represent type III hypersensitivity reactions to circulating immune complexes that lead to infiltration of vessel walls by inflammatory cells. Orbital involvement usually leads to significant morbidity and is typically associated with systemic vasculitis. The following discussion focuses mainly on the orbital manifestations of the vasculitides. See also BCSC Section 1, *Update on General Medicine*; Section 5, *Neuro-Ophthalmology*; and Section 9, *Uveitis and Ocular Inflammation*.

Giant cell arteritis

Although not typically thought of as an orbital disorder, giant cell arteritis (GCA; also called *temporal arteritis*) involves inflammation of the orbital vessels and should be considered an urgent ophthalmic condition. The vasculitis affects the aorta, vertebral arteries, and branches of the external and internal carotid arteries; however, it typically spares the intracranial carotid artery branches, which lack an elastic lamina. Vision loss may occur from central retinal artery occlusion or ischemic optic neuropathy, and diplopia may result from ischemic dysfunction of associated cranial nerves. Systemic manifestations include headache, scalp tenderness, jaw claudication, and constitutional symptoms.

The combined sensitivity of erythrocyte sedimentation rate (ESR) and C-reactive protein testing may be as high as 99%, and thrombocytosis (platelet count) greater than 400×10^3 µL supports the diagnosis. However, temporal artery biopsy represents the gold standard for diagnosis (Video 4-1). Biopsies may contain intervals of normal tissue between affected segments, and discordant biopsy may occur after bilateral biopsy. For these reasons, bilateral biopsy and specimens of increased length have been advocated by some; however, no consensus exists.

VIDEO 4-1 Temporal artery biopsy.
Courtesy of Julian D. Perry, MD, and Alexander D. Blandford, MD.

Because serologic testing may be negative in some cases, and because devastating progression may occur without treatment, administration of high-dose corticosteroids should begin as soon as possible when GCA is suspected. Tocilizumab, a monoclonal IL-6 receptor antibody, can induce and maintain remission with a shorter corticosteroid taper. Risks associated with biopsy include scarring, hemorrhage, and cranial nerve VII frontal branch injury that produces paralytic lagophthalmos or brow ptosis, especially if nerve injury occurs proximal to its course over the zygoma.

Stone JH, Tuckwell K, Dimonaco S, et al. Trial of tocilizumab in giant-cell arteritis. *N Engl J Med*. 2017;377(4):317–328.

Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) is a multisystem disease characterized by necrotizing granulomatous inflammation and vasculitis of small- to medium-sized vessels. Although the disease often affects the respiratory and renal systems, it can affect any body site. Orbital involvement occurs in 45%–60% of patients with GPA and represents the most common ophthalmologic manifestation of the disease.

GPA typically presents clinically as either a systemic generalized disease or in a more limited form. The generalized form may produce sinusitis with or without bone erosion, tracheobronchial necrotic and stenotic lesions, cavitary lung lesions, and glomerulonephritis (Fig 4-13). It is unclear whether the limited form of the disease represents a distinct clinical entity or is a subtype of the general form. Either form can extend from the

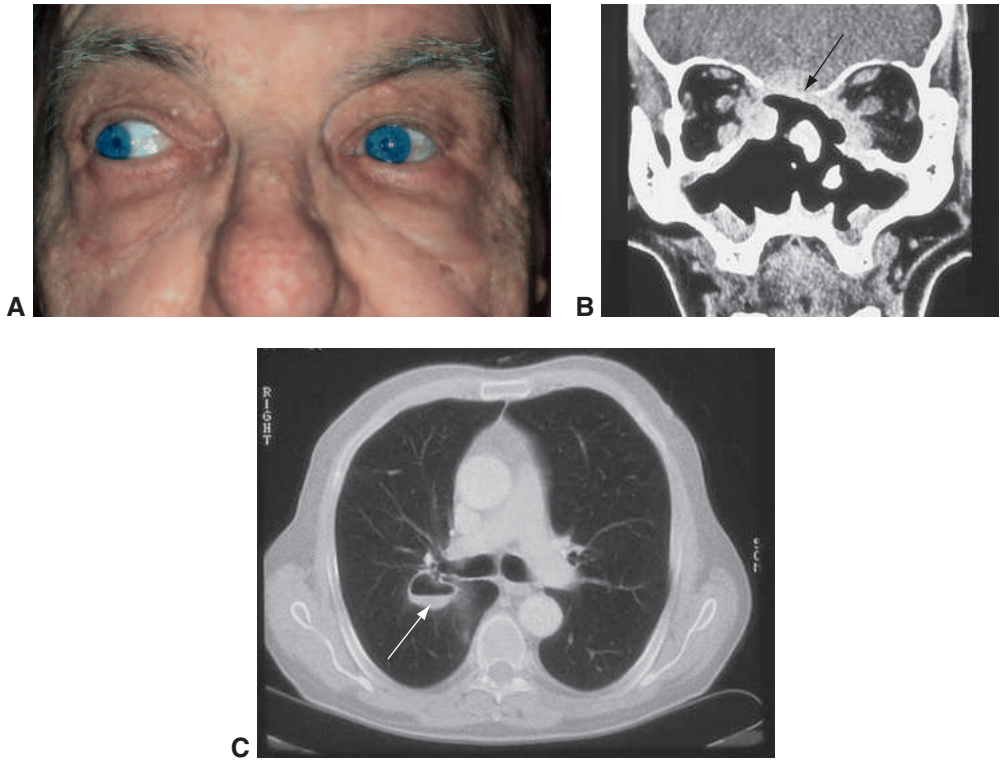

Figure 4-13 Granulomatosis with polyangiitis (GPA). **A,** Patient with restrictive strabismus of the left eye due to inflammatory tissue extending into the medial aspects of the orbit. **B,** Coronal CT scan shows extensive destruction of the nasal and sinus cavities with inflammatory tissue extending into orbits and brain *(arrow)*. **C,** CT of chest shows cavitary lung lesions *(arrow)*. *(Courtesy of Jeffrey A. Nerad, MD.)*

surrounding sinuses to involve the orbit and nasolacrimal drainage system, but the limited form causes approximately two-thirds of orbital GPA cases.

Histologic examination, especially in cases of isolated orbital involvement, may not always show the classic triad of vasculitis, granulomatous inflammation (with or without giant cells), and tissue necrosis. Often, only 1 or 2 of these findings is present on extrapulmonary biopsies.

Although their exact pathogenic role remains unclear, antineutrophil cytoplasmic autoantibodies (ANCAs) are strongly associated with certain vasculitides, including GPA. Testing for ANCAs distinguishes 2 types of immunofluorescence patterns.

- Diffuse granular fluorescence within the cytoplasm (c-ANCA) is highly specific for GPA. This pattern is caused by autoantibodies directed against proteinase-3, which can then be measured by enzyme-linked immunosorbent assay (ELISA).
- Fluorescence surrounding the nucleus (p-ANCA) is an artifact of ethanol fixation and can be caused by autoantibodies against many different target antigens. This finding is therefore nonspecific and needs to be confirmed by ELISA for ANCA reacting with myeloperoxidase (MPO-ANCA). MPO-ANCA testing has moderate specificity for small-vessel vasculitis but may return a positive result in patients with nonvasculitic diseases such as rheumatoid arthritis, sarcoidosis, or systemic lupus erythematosus.

Although highly specific for GPA, c-ANCA tests possess less sensitivity, especially in cases of isolated sino-orbital GPA and in inactive disease. Unlike c-ANCA–positive disease, p-ANCA–positive disease rarely affects the eye and orbit. Absolute levels of ANCA do not define disease severity or activity, and the use of titers to monitor for response to therapy, remission, and relapse remains controversial.

Treatment of GPA relies on remission-induction therapy, which often employs cytotoxic agents (eg, cyclophosphamide) and corticosteroids, followed by remission-maintenance therapy, which often uses methotrexate, azathioprine, and corticosteroids. Long-term treatment with TMP-SMX appears to suppress disease activity in some patients, and rituximab may help induce remission, although relapses are common regardless of treatment. Patients require care coordination from a rheumatologist because both GPA and its treatment can produce life-threatening effects.

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is a multisystem disease in which small- and medium-sized arteries are affected by inflammation characterized by the presence of neutrophils and eosinophils, and necrosis of the muscularis layer. Although PAN may affect multiple organ systems, the disease rarely produces orbital inflammation. Ophthalmic manifestations more commonly result from retinal and choroidal infarction.

Sarcoidosis

Sarcoidosis, which is characterized by collections of noncaseating granuloma, can affect any organ, most commonly the lungs. In the United States, the disease occurs 3 to 4 times

more frequently in individuals of African descent than in those of European or Asian descent. It can also affect the orbit, most frequently the lacrimal gland (typically bilaterally) (Fig 4-14). Gallium scanning, although nonspecific, shows lacrimal gland involvement in 80% of patients with systemic sarcoidosis, although only 7% of patients demonstrate clinically detectable lacrimal gland enlargement. Subconjunctival nodules (Fig 4-15A, B) and other orbital soft tissues, including the extraocular muscles and optic nerve, are involved only in rare cases. Infrequently, there is sinus involvement, with associated lytic bone lesions invading the adjacent orbit. The disease may also affect the nasolacrimal drainage system and result in nasolacrimal duct obstruction.

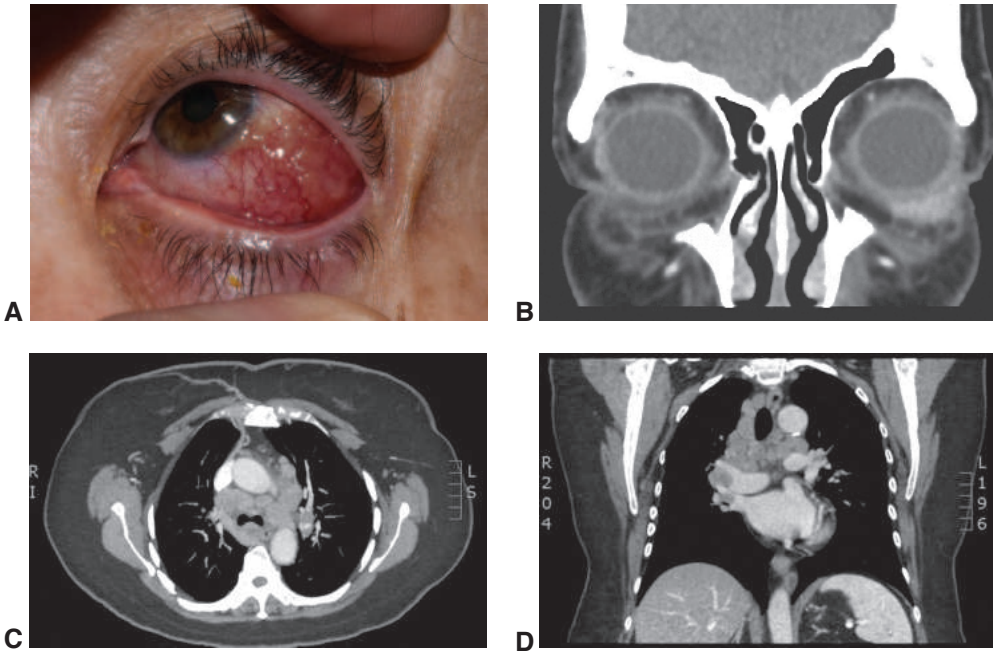

Figure 4-15 Sarcoidosis. **A,** Sarcoidosis presenting in a patient as left subconjunctival nodules. **B,** Orbital coronal CT scan shows the lesion in the anterior orbit. **C** and **D,** CT scans of the chest show bilateral hilar adenopathy. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Key ancillary testing would include:

- Chest radiography, CT, or gallium scans: These may detect hilar adenopathy or pulmonary infiltrates (Fig 4-15C, D).
- Serologic testing: Blood work may show elevated levels of angiotensin-converting enzyme (ACE), lysozyme, and calcium. ACE is produced by the epithelioid cells and macrophages found in sarcoid granulomas, so the ACE level reflects the mass of granulomas in the body and the severity of sarcoidosis.
- Tissue biopsy: Regardless of serologic and imaging findings, when possible, it may be best to confirm the diagnosis with tissue biopsy. Biopsy of an affected lacrimal gland or of a suspicious conjunctival lesion may establish the diagnosis; however, random conjunctival biopsies have a low yield.
- Bronchoscopy with bronchial washing and biopsy: Results may confirm pulmonary involvement.

Histologic examination reveals noncaseating collections of epithelioid histiocytes in a granulomatous pattern, with mononuclear cells often appearing at the periphery of the granuloma.

Isolated orbital lesions can occur without associated systemic disease; this condition is called orbital sarcoidosis. Interestingly, patients with either isolated or systemic sarcoidosis involving the orbit rarely develop intraocular involvement and vice versa.

See BCSC Section 9, *Uveitis and Ocular Inflammation,* for more extensive discussion and clinical photographs of sarcoidosis.

Immunoglobulin G4–Related Disease

Immunoglobulin G4–related disease (IgG4-RD) is a fibroinflammatory disorder that may affect 1 or more organs (Fig 4-16, 4-17). Orbital disease may occur alone or with systemic disease, either synchronously or at different times. Within the orbit, the disease most commonly

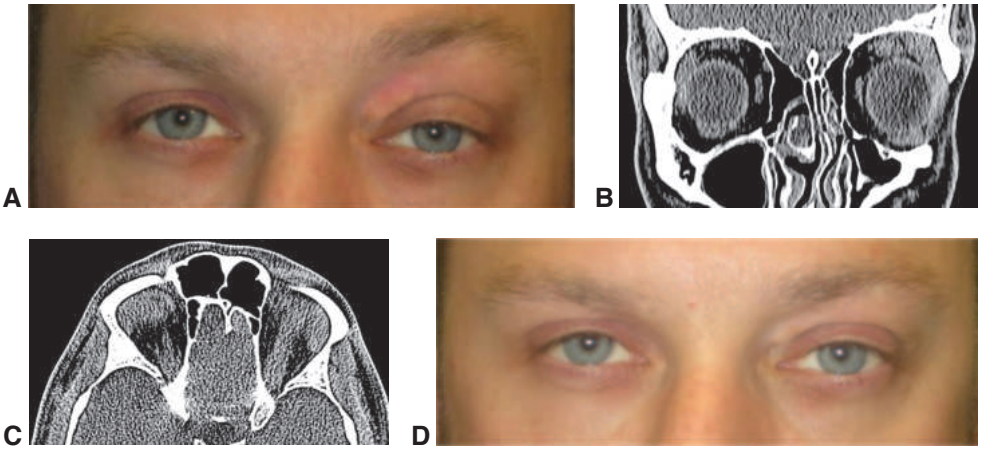

Figure 4-16 Immunoglobulin G4–related disease (IgG4-RD) of the lacrimal gland. **A,** Photograph of a patient with left-side proptosis. **B** and **C,** Axial and coronal CT imaging studies, respectively, show enlargement of the left lacrimal gland region. **D,** Patient improvement after immunosuppressive treatment. *(Courtesy of Julian D. Perry, MD, and Alexander D. Blandford, MD.)*

affects the lacrimal gland, and orbital involvement occurs in common patterns, including the following:

- enlargement of the orbital nerves (typically the infraorbital nerve), extraocular muscles, and lacrimal gland, often with sinusitis, peripheral eosinophilia, and systemic involvement
- sclerosing dacryoadenitis (unilateral or bilateral) (see Fig 4-17)
- sclerosing orbital inflammation without dacryoadenitis

Histologic examination shows lymphoplasmacytic infiltrates with large numbers of immunoglobulin G4 (IgG4)-positive plasma cells, storiform fibrosis, obliterative phlebitis, and eosinophil infiltration. A consensus statement of international subspecialists in rheumatology, pathology, radiology, ophthalmology, pulmonary medicine, and other specialties set the minimum number of IgG4-positive plasma cells for the lacrimal gland at greater than 100 per high-power field; however, many published series report smaller numbers of cells. In most cases, the ratio of IgG4 to IgG plasma cells is greater than 40%. Given the spectrum of histologic findings, the diagnosis of IgG4-RD requires integrating clinical, imaging, and histopathologic criteria.

About half of patients with the orbital disease will also have disease in other organs. Rheumatological evaluation often includes examination for salivary gland, lymph node, lung, liver, and retroperitoneal involvement using various imaging studies, including CT, MRI, and CT-PET (positron emission tomography) scanning. Serologic testing may show peripheral eosinophilia and elevated IgG4 levels.

Treatment includes the use of corticosteroids and other immunosuppressants and biologic agents, including rituximab. Another monoclonal antibody that targets CD19 shows promise to treat this condition as well.

Immunoglobulin G4–related disease comprises a significant proportion of what was previously categorized as nonspecific orbital inflammation; thus, biopsy of orbital inflammatory lesions should routinely include an examination for features of IgG4-RD. With greater understanding of inflammatory disease, other conditions currently considered nonspecific orbital inflammation may be elucidated.

Nonspecific Orbital Inflammation

Diagnosis of nonspecific orbital inflammation (NSOI, also known as idiopathic orbital inflammation, and historically referred to as orbital pseudotumor) remains a diagnosis of exclusion, made only after all specific causes of inflammation have been eliminated. The condition is characterized by a polymorphous lymphoid infiltrate with varying degrees of fibrosis, without a known local or systemic cause.

Although controversial, the pathogenesis of NSOI appears to be immune-mediated due to its association with systemic immunologic disorders, including Crohn disease, systemic lupus erythematosus, rheumatoid arthritis, diabetes mellitus, myasthenia gravis, and ankylosing spondylitis. In addition, NSOI typically responds rapidly to treatment with corticosteroids and other immunosuppressive agents, indicating a cell-mediated component.

The symptoms and clinical findings in NSOI vary depending on the degree and anatomical location of the inflammation. In order of frequency, NSOI tends to occur in the 5 following orbital locations or patterns:

- extraocular muscles *(myositis)*
- lacrimal gland *(dacryoadenitis)* (Fig 4-18)
- anterior orbit (eg, *scleritis*)
- orbital apex
- throughout the orbit (as diffuse inflammation)

Although it is usually limited to the orbit, NSOI may also extend into the adjacent sinuses or intracranial space. Deep, boring pain occurs in many cases; pain associated with ocular movement suggests myositis. Symptoms of vision impairment may occur with involvement of the optic nerve or posterior sclera. Signs include extraocular muscle restriction, proptosis, conjunctival inflammation, chemosis, and erythema and edema of the eyelid (Fig 4-19).

Diagnosis

Imaging studies such as CT, MRI, and ultrasonography reveal enlargement of affected tissues and may show other characteristic findings. Up to 50% of cases show thickening of the extraocular muscle tendon insertions (Fig 4-20; see also Fig 4-19), in contrast with TED, which typically spares the muscle insertions. Involvement of the retrobulbar fat pad may produce fat stranding, and tendonitis may produce contrast enhancement of the sclera. B-scan ultrasonography often shows an acoustically hollow area that corresponds to an edematous Tenon capsule; this is called T-sign.

Figure 4-18 Nonspecific orbital inflammation (NSOI) demonstrating left eyelid edema, erythema, and lateral ptosis secondary to inflammation of the left lacrimal gland (dacryoadenitis). *(Courtesy of Cat N. Burkat, MD.)*

A prompt initial response to high-dose (1 mg/kg oral prednisone or equivalent) systemic corticosteroids supports the diagnosis; this response is observed in most myositic cases and in about 80% of nonmyositic cases. However, inflammation associated with other orbital processes (eg, metastases, lymphoma, ruptured dermoid cysts, infections) may also improve with systemic corticosteroid administration. In 1 study, 50% of biopsied inflammatory lacrimal gland lesions were associated with systemic disease, including GPA, sclerosing inflammation, Sjögren syndrome, sarcoid, and Lyme and autoimmune disease.

Carter, MD; parts B and C courtesy of Robert C. Kersten, MD.)*

Figure 4-20 Axial CT scan shows myositis of the left medial rectus muscle with involvement of the tendon *(arrow)*. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Given the low morbidity associated with biopsy, the possibility of other orbital processes responding to treatment with corticosteroids, and the high incidence of systemic disease involving the lacrimal gland, many experts recommend diagnostic biopsy of all nonmyositic lesions not attached to the optic nerve. Surgical debulking of idiopathic dacryoadenitis during the biopsy procedure may carry a therapeutic as well as a diagnostic benefit.

In cases of myositis, lesions attached to the optic nerve and lesions involving the orbital apex may produce characteristic clinical and radiographic findings to strongly support the presumed diagnosis, and the risk associated with biopsy may outweigh the risk of a missed diagnosis.

Not all patients with NSOI present with the classic signs and symptoms; some patients present with atypical pain, limited inflammatory signs, or a fibrotic variant called *sclerosing NSOI.* Simultaneous bilateral orbital inflammation in adults suggests the possibility of systemic vasculitis. Any diagnostic uncertainty mandates a thorough systemic evaluation.

In children with NSOI, approximately one-third of cases present bilaterally and approximately one-half present with systemic signs, such as headache, fever, vomiting, abdominal pain, and lethargy. Uveitis, elevated ESR levels, and eosinophilia are also more common in children with NSOI. Pediatric NSOI is not generally associated with systemic disorders.

On histologic examination, NSOI is characterized by a pleomorphic cellular infiltrate consisting of lymphocytes, plasma cells, and eosinophils with variable degrees of reactive fibrosis. The sclerosing subtype of NSOI demonstrates a predominance of fibrosis with sparse cellular inflammation. Hypercellular lymphoid proliferations represent clinical and histologic entities that are different from NSOI.

Mombaerts I, Bilyk JR, Rose GE, Expert Panel of the Orbital Society, et al. Consensus on diagnostic criteria of idiopathic orbital inflammation using a modified Delphi approach. *JAMA Ophthalmol.* 2017;135(7):769–776.

Treatment

As previously discussed, initial therapy for NSOI consists of systemic corticosteroids, with a typical initial daily adult dosage of 1 mg/kg prednisone. Acute cases generally respond rapidly, with abrupt resolution of pain. Steroid taper begins after maximal clinical response; it should proceed more slowly at dosages less than about 40 mg/day and even slower at less than 20 mg/day, based on the clinical response. Rapid reduction of systemic steroids may allow for recurrence. Some investigators believe that pulse-dosed IV dexamethasone followed by oral prednisone may produce clinical improvement when oral prednisone alone fails to control the inflammation. Sclerosing NSOI responds poorly to steroids and to low-dose fractionated radiotherapy; it typically requires more aggressive immunosuppression with agents such as cyclosporine, methotrexate, or cyclophosphamide. Table 4-5 summarizes the recommended serologic testing for the autoimmune orbital conditions discussed.

Mombaerts I, Rose GE, Garrity JA. Orbital inflammation: biopsy first. *Surv Ophthalmol.* 2016;61(5):664–669.

Table 4-5 Recommended Serologic Testing for Autoimmune Orbital Conditions

Autoimmune Disease	Serologic Test
Giant cell arteritis	Erythrocyte sedimentation rate (ESR) C-reactive protein (CRP)
Granulomatosis with polyangiitis	c-ANCA MPO-ANCA Proteinase 3 (PR3) Platelets
Polyarteritis nodosa	None (though negative ANCA and elevated blood urea nitrogen can be useful)
Sarcoidosis	Angiotensin-converting enzyme (ACE) Lysozyme Calcium
Immunoglobulin G4–related disease	IgG4 (suggestive but not necessary to confirm disease)
Sjögren	Antinuclear antibodies (ANA) SS-A (Ro), SS-B (La)
Nonspecific orbital inflammation (NSOI)	(Diagnosis of exclusion)

CHAPTER 5

Orbital Neoplasms and Malformations

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- The orbit is a rigid, confined space, and lesions that originate in or infiltrate the orbit often present with ophthalmic manifestations.
- Pathology can occur in any orbital tissue, including bone, vasculature, nerves, muscle, and the lacrimal gland.
- Careful history taking provides diagnostic clues, as certain lesions present more commonly in different age groups.
- Imaging of the orbit and surrounding sinuses and intracranial cavity helps guide diagnosis and management.
- Understanding the hemodynamics of vascular lesions is critical for safe and effective treatment.

Vascular Tumors, Malformations, and Fistulas

Infantile (Capillary) Hemangioma

Infantile (capillary) hemangiomas are common primary benign tumors of the orbit in children (Fig 5-1). These lesions present at birth or within the first few weeks of life. They enlarge dramatically over the first 6–12 months and begin to involute after the first year of life; 75% of lesions resolve by the age of 3–7 years. Female sex, low birth weight, prematurity, and historically maternal chorionic villus sampling are associated with infantile hemangiomas, although etiology remains unclear.

Congenital infantile hemangiomas may be superficial—in which case they involve the skin and appear as a bright red, soft mass with a dimpled texture—or they may be subcutaneous and bluish. Hemangiomas located deeper within the orbit may present as a progressively enlarging mass without any overlying skin change. Magnetic resonance imaging (MRI) may help to distinguish infantile hemangiomas from other vascular malformations by demonstrating characteristic fine intralesional vascular channels and high blood flow. Color

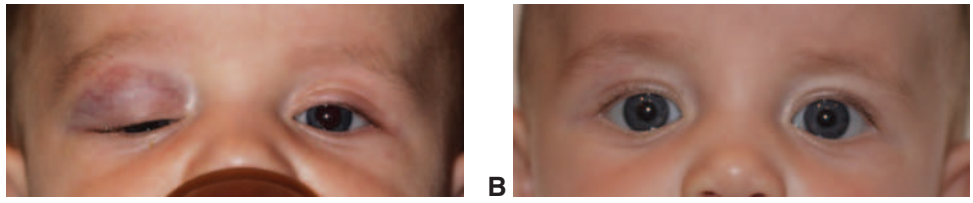

Figure 5-1 Infantile (capillary) hemangioma. **A,** Infantile hemangioma involving the right upper eyelid. **B,** Marked regression of lesion 6 weeks after initiation of propranolol therapy. *(Courtesy of William R. Katowitz, MD.)*

Doppler ultrasound imaging is a reliable and inexpensive imaging tool for diagnosing these lesions, often showing numerous blood vessels within the mass and abundant blood flow.

In the periocular area, infantile hemangiomas occur most commonly in the superonasal quadrant of the orbit and the medial upper eyelid (see also the section Congenital Eyelid Lesions in Chapter 10). They may be associated with hemangiomas on other parts of the body; lesions that involve the neck can compromise the airway and lead to respiratory obstruction, and multiple large visceral lesions can produce thrombocytopenia.

Management

Most lesions regress spontaneously, requiring only observation with refractive correction and amblyopia therapy. The main ocular complications of infantile hemangiomas are amblyopia, strabismus, and anisometropia. Although disruption of vision or severe disfigurement may require therapy, treatment can be deferred until it is clear that such complications may develop.

For infantile hemangiomas that require therapy, β-blockers are the first-line treatment. Topical timolol gel treats superficial tumors and has limited systemic adverse effects. Oral propranolol treats deeper lesions and has fewer adverse effects than systemic steroids, although life-threatening hypotension, bradycardia, and hypoglycemia can occur in rare instances. Oral β-blocker treatment should be initiated under the guidance of a pediatrician so that the patient can be monitored for systemic adverse effects. Lesions that do not respond adequately to β-blockers may require treatment with steroids administered topically, by local injection, or orally (see the section Congenital Eyelid Lesions in Chapter 10). Adverse effects of steroid injection include skin necrosis, subcutaneous fat atrophy, and retinal embolic vision loss. Steroid treatment by any route in infants may produce hypothalamic-pituitary-adrenal axis suppression, systemic growth retardation, and other metabolic adverse effects.

Surgical excision may be considered for active-phase lesions refractory to steroids or for some smaller or subcutaneous nodular lesions. Pulsed-dye laser therapy can improve superficial components of the hemangioma. Radiation therapy has also been used but can lead to cataract formation, bony hypoplasia, tissue scarring, and future malignancy. Sclerosing solutions are typically not recommended, as they can cause severe scarring. Residual lesions that remain after involution or treatment can be removed surgically.

Lymphatic Malformation

Pure lymphatic malformations (LMs; previously called *lymphangiomas*) are low-flow orbital lesions that result from disruption of the initially pluripotent vascular anlage; these LMs

lead to aberrant development and congenital malformation. LMs can also occur in the conjunctiva (Fig 5-2A), eyelids, oropharynx (Fig 5-2B), and sinuses. In the orbit, LMs usually become apparent in the first or second decade of life. They can be described as *macrocystic* (cysts ≥ 2 cm), *microcystic* (cysts < 2 cm), or *mixed macrocystic/microcystic*. LMs cannot be decompressed and do not distend with a Valsalva maneuver. However, they may enlarge during upper respiratory tract infections, and they may present with sudden proptosis caused by spontaneous intralesional hemorrhage *(chocolate cysts)*.

The natural history of LMs is variable; some are localized and progress slowly, whereas others may diffusely infiltrate orbital structures and enlarge inexorably. MRI may show pathognomonic features (multiple grapelike cystic lesions with fluid–fluid layering of serum and red blood cells), confirming the diagnosis (Fig 5-2C).

LMs are characterized by their hemodynamic properties, and classification schemes continue to evolve. Some LMs possess a significant venous flow component and have clinical characteristics that overlap with those of venous malformations (VMs, discussed later in

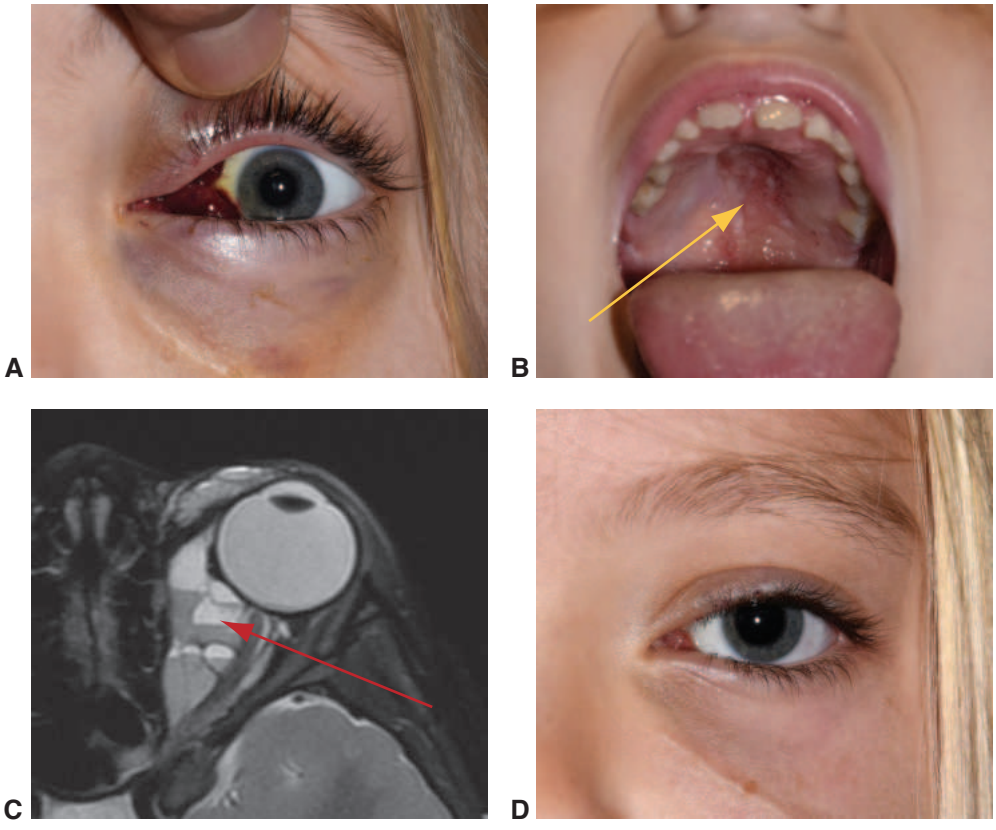

Figure 5-2 Lymphatic malformation. **A,** External photograph shows lymphatic malformation presenting as a hemorrhagic subconjunctival mass. **B,** Involvement of the hard palate *(arrow)*. **C,** T2-weighted axial magnetic resonance image (MRI) shows multiple saccular lesions with serum and blood fluid levels *(arrow)* medial to the optic nerve. **D,** External photograph after injection with bleomycin. *(Courtesy of Bobby S. Korn, MD, PhD.)*

this chapter); these lesions are termed *combined lymphatic venous malformations*. Treatment depends on the hemodynamic flow characteristics of the lesion.

Histologically, pure LMs are characterized by serum-filled channels lined by flat endothelial cells that have immunostaining patterns consistent with lymphatic capillaries. Scattered follicles of lymphoid tissues are found in the interstitium. These lesions have an infiltrative pattern and are not encapsulated.

Management

Treatment of LM is challenging for several reasons:

- The vascular channels are typically not amenable to endovascular approaches.
- The infiltrative nature of the lesion often involves vital orbital structures.
- Significant hemorrhage may occur during surgery.
- Recurrence is common.

Observation is a reasonable approach for lesions that are asymptomatic and not amblyogenic. If treatment is warranted, debulking of the lesion combined with use of sclerosing agents, either percutaneous or intraoperatively, may be successful. Sclerosants include morrhuate sodium, bleomycin (Fig 5-2D), polidocanol, OK-432, thrombosing agents such as fibrin glue, and embolizing agents such as cyanoacrylate glues and ethylene vinyl alcohol copolymer.

Acute hemorrhage complicated by optic neuropathy or corneal ulceration may respond to ultrasound-guided aspiration of blood through a hollow-bore needle or by open surgical exploration. While mild hematomas may resolve spontaneously, the mass effect of such hemorrhages can persist due to bleeding within dead-end lymphatic channels.

Noncontiguous intracranial vascular malformations have been reported in up to 25% of patients with orbital LMs. These lesions have a low rate of spontaneous hemorrhage and are not treated prophylactically.

Distensible Venous Malformation

Distensible venous malformations of the orbit, previously known as *orbital varices*, are low-flow lesions that enlarge with a Valsalva maneuver (Fig 5-3). Patients may exhibit enophthalmos at rest, when the lesion is not engorged. Proptosis that increases when the patient's head is dependent or after a Valsalva maneuver suggests the presence of a venous malformation (Fig 5-3A, B). Apart from the inducible proptosis, the ophthalmic examination is often unremarkable, with symmetric intraocular pressures (IOPs), lack of conjunctival vessel engorgement, fullness of the eyelid (Fig 5-3C), and no reflux of blood in the Schlemm canal. The diagnosis can be confirmed with imaging such as MRI (Fig 5-3D) or contrast-enhanced rapid spiral computed tomography (CT) during a Valsalva maneuver or other means of decreasing venous return; cases show characteristic enlargement of the engorged veins. Phleboliths may be present on imaging.

Management

Management is usually conservative, with only observation of relatively asymptomatic lesions. Biopsy should be avoided because of the risk of hemorrhage. Surgery is reserved for patients who have significant pain or in whom the malformation causes vision-threatening

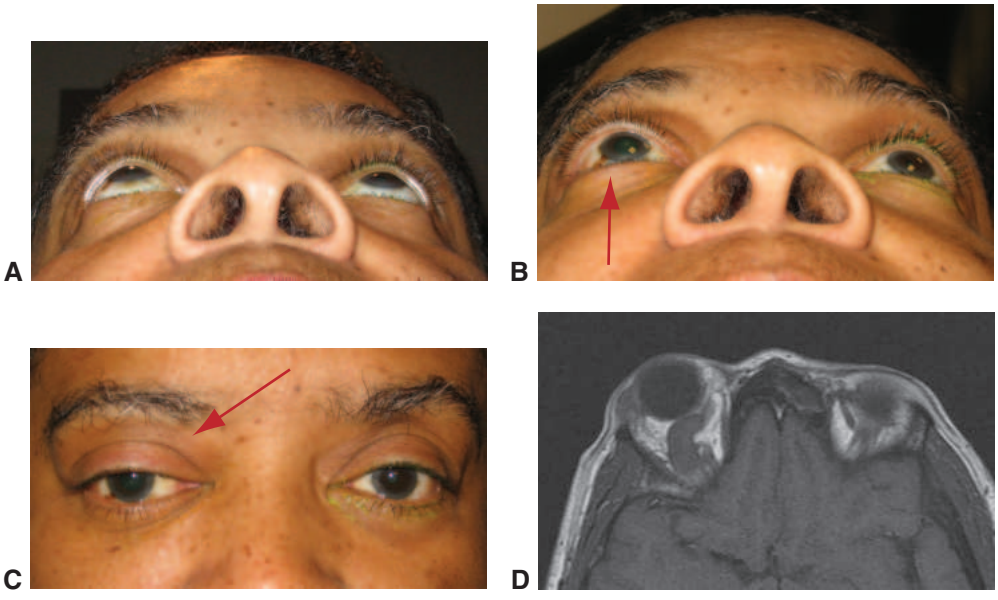

Figure 5-3 Distensible venous malformation. **A,** Mild proptosis resulting from venous malformation of the right orbit. **B,** After Valsalva maneuver, proptosis of the right globe increases *(arrow).* **C,** Fullness of the right superior orbit *(arrow).* Note the absence of dilated corkscrew conjunctival vessels. **D,** T1-weighted axial MRI shows a venous malformation of the superior ophthalmic vein. *(Courtesy of Bobby S. Korn, MD, PhD.)*

compressive optic neuropathy. Complete surgical excision is difficult, as these lesions often intertwine with normal orbital structures and directly communicate with the abundant venous reservoir in the cavernous sinus. Treatment of highly symptomatic lesions typically consists of combined embolization and excision. Sclerosants, injected either percutaneously or directly through an open approach, are an additional treatment option. However, orbital compartment syndrome, which requires urgent decompression, may occur.

Cavernous Venous Malformation

Cavernous venous malformations (CVMs) are nondistensible, low-flow vascular lesions previously known as *cavernous hemangiomas*. They are the most common type of primary orbital lesion in adults and typically present in the fourth and fifth decades of life. Women represent 60% of cases; circulating estrogen and progesterone levels may play a role in clinical progression, with growth sometimes accelerating during pregnancy.

CVMs typically produce slowly progressive, painless proptosis (Fig 5-4A). Other findings may include:

- choroidal folds
- hyperopia
- optic nerve compression
- increased IOP
- strabismus

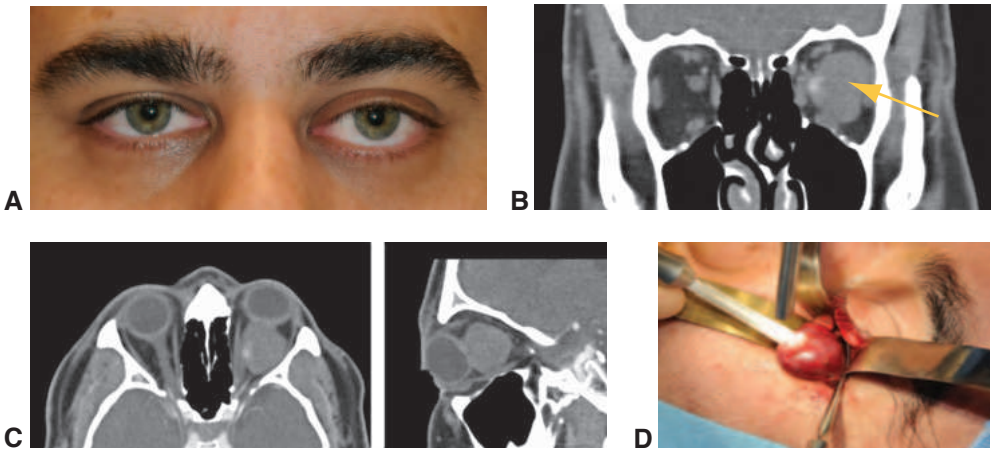

Figure 5-4 Cavernous venous malformation (CVM). **A,** Proptosis of the left eye as a result of CVM. **B,** Coronal computed tomography (CT) scans show a well-circumscribed lesion in the muscle cone *(arrow).* **C,** Axial *(left)* and sagittal *(right)* CT scans show the intraconal mass. **D,** Intraoperative traction with a cryoprobe facilitates complete removal of the mass. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Contrast-enhanced orbital imaging shows a stippled pattern in the early phase of contrast that develops into homogeneous staining in the late phase. The lesion appears as a well-circumscribed mass that can have an intraconal and/or extraconal component (Fig 5-4B, C). Chronic lesions may contain radiodense phleboliths. Arteriography and venography typically do not aid in the diagnosis as these lesions have very limited communication with the systemic circulation.

On histologic examination, CVMs are encapsulated and composed of large, cavernous spaces with walls of smooth muscle containing red blood cells.

Management

Treatment consists of complete surgical excision if the lesion compromises visual function, causes significant proptosis, or demonstrates substantial growth. The growth potential of a CVM is not predictable at the time of diagnosis or following incomplete resection; in rare cases, these lesions may involute spontaneously.

Because they are encapsulated and relatively isolated from the surrounding tissue, CVMs are often easier to remove than many other orbital tumors. Coronal imaging helps determine the position of the CVM relative to the optic nerve, and the surgical approach is dictated by the location of the lesion (Fig 5-4D). Deeper lesions may be attached to vital (and sometimes vascular) structures within the orbital apex, so their complete excision may not always warrant the associated risks. Radiotherapy can be considered for lesions located deep within the orbital apex.

Rootman J, Heran MK, Graeb DA. Vascular malformations of the orbit: classification and the role of imaging in diagnosis and treatment strategies. *Ophthalmic Plast Reconst Surg.* 2014;30(2):91–104.

Arteriovenous Malformation

Arteriovenous malformations (AVMs) are high-flow developmental anomalies that, like venous malformations, result from vascular dysgenesis. They are characterized by rapid arterial flow through the nidus into the draining venous circulation and often occur in choke anastomotic zones. Dilated corkscrew episcleral vessels and pulsatile proptosis may be present, and vascular steal or shunting from the orbit may produce ischemic changes. Noninvasive imaging supports the diagnosis, with CT revealing diffuse enhancement and MRI showing flow voids (Fig 5-5).

Management

AVMs gradually enlarge as they recruit more arterial feeders. They often require treatment, which involves preoperative selective angiography with embolization followed by resection of the nidus. Failure to completely resect the nidus may allow recurrence; however, complete resection of the nidus may not be possible without significant morbidity. Exsanguinating arterial hemorrhage can occur with surgical intervention, especially in unsuspected lesions without preoperative embolization.

Arteriovenous Fistula

Arteriovenous fistulas are acquired lesions characterized by abnormal direct communication between an artery and a vein without flow through an intervening capillary bed. An

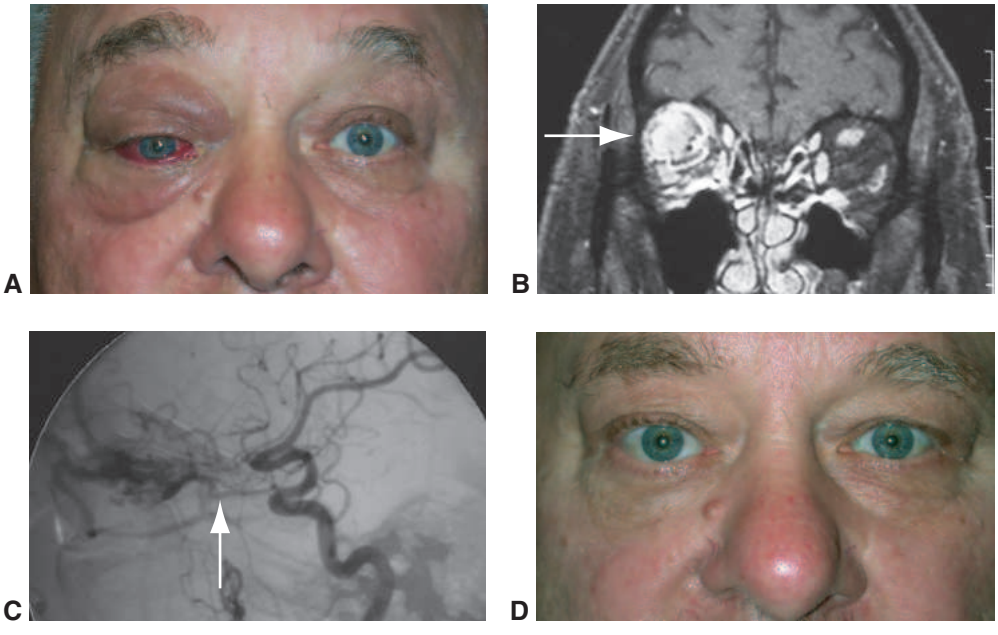

Figure 5-5 Arteriovenous malformation. **A,** Arteriovenous malformation in the right eye causing proptosis and arterialization of conjunctival vessels. **B,** T1-weighted, gadolinium-enhanced MRI shows enhancing superolateral nidus of lesion *(arrow)*. **C,** Angiogram shows enlarged ophthalmic artery *(arrow)*. **D,** Proptosis and arterialized vessels are resolved after embolization and excision of nidus. *(Courtesy of Julian D. Perry, MD, and Alexander D. Blandford, MD.)*

arteriovenous fistula may be caused by trauma or degeneration. There are 2 forms, direct and indirect (dural) (Table 5-1).

Direct carotid-cavernous fistulas are characterized by a connection between the internal carotid artery and the cavernous sinus; they typically occur after trauma that creates a tear or hole in a branch artery of the internal carotid within the cavernous sinus. They may also be caused iatrogenically, for example, during neurosurgical or neuroradiologic procedures.

Direct carotid-cavernous fistulas possess high blood flow and may produce characteristic tortuous epibulbar vessels as well as pulsatile proptosis and an audible bruit. Ischemic ocular damage results from diversion of arterialized blood into the venous system, which causes venous outflow obstruction (Fig 5-6A). This in turn leads to elevated IOP, choroidal effusions, blood in the Schlemm canal, and nongranulomatous anterior uveitis. Ocular motility abnormalities can result from either congestion within the orbit or increased pressure in the cavernous sinus. The latter can cause compression of cranial nerves III, IV, and, most commonly, VI, with associated extraocular muscle palsies. CT scans may show diffuse enlargement of some or all of the extraocular muscles as a result of venous engorgement and a characteristically enlarged superior ophthalmic vein (Fig 5-6B, C).

Indirect (dural) carotid-cavernous fistulas are characterized by a connection between meningeal branches of the internal and/or external carotid artery and the cavernous sinus. These fistulas most commonly develop as a degenerative process in older patients with systemic hypertension, vascular disease, and/or atherosclerosis. Because dural fistulas generally have lower rates of blood flow than direct carotid-cavernous fistulas, their onset can be insidious, with only mild orbital congestion, proptosis, and pain. Arterialization of the conjunctival veins causes chronic red eye. Increased episcleral venous pressure results in asymmetric elevation of IOP on the affected side, and patients with chronic fistulas are at risk for glaucomatous optic neuropathy.

Magnetic resonance angiography (MRA) may be helpful in diagnosing arteriovenous fistulas, with fewer associated adverse effects than conventional angiography (eg, stroke). However, conventional angiography possesses more sensitivity than MRA and remains the gold standard for diagnosis.

Management

The decision to treat an arteriovenous fistula is based on weighing the severity of symptoms against the risks associated with intervention. Because they are high-flow lesions, direct carotid-cavernous fistulas usually require intervention. Small indirect carotid-cavernous fistulas often close spontaneously and may initially be observed. However, because even these lesions may result in intracranial hemorrhage, some investigators have recommended more aggressive management of indirect fistulas.

Intervention typically involves an endovascular treatment (coils or glue) to block the fistula (Fig 5-6D). Transvenous access is used to reach dural fistulas, while direct carotid-cavernous fistulas are generally treated via a transarterial approach. Occasionally, a transvenous approach by transcutaneous canalization of the superior ophthalmic vein is employed for embolization, which may require an orbitotomy to directly access the vein.

See BCSC Section 5, *Neuro-Ophthalmology,* for additional discussion of carotid-cavernous fistulas.

Table 5-1 Arteriovenous Fistula

Form of arteriovenous fistula	Abnormal vascular connection	Flow	Typical etiology	Onset	Anterior segment vessels	Key clinical findings	Imaging
Direct carotid-cavernous fistulas	Between internal carotid artery and cavernous sinus	High blood flow rate	After trauma that creates a tear in a branch artery of the internal carotid within the cavernous sinus Iatrogenic, during neurosurgical procedures	Rapid	Characteristic tortuous epibulbar vessels	Pulsatile proptosis Audible bruit Elevated intraocular pressure Choroidal effusions Blood in Schlemm canal Ocular dysmotility (cranial nerve VI palsy > cranial nerves III, IV)	Diffuse enlargement of extraocular muscles due to venous engorgement Characteristic enlarged superior ophthalmic vein
Indirect (dural) carotid-cavernous fistulas	Between meningeal branches of internal and/or external carotid artery and cavernous sinus	Low blood flow rate	Degenerative process in older patients with systemic hypertension, vascular disease, atherosclerosis	Insidious	Chronic red eye	Mild orbital congestion Mild proptosis Minimal pain Increased episcleral venous pressure and asymmetric intraocular pressure elevation	Diffuse enlargement of extraocular muscles due to venous engorgement Characteristic enlarged superior ophthalmic vein

Korn, MD, PhD.)*

Orbital Hemorrhage

An orbital hemorrhage may result from trauma, surgery, or spontaneous bleeding from vascular malformations or orbital metastasis (Fig 5-7). In rare instances, a spontaneous hemorrhage may be caused by a sudden increase in venous pressure (eg, due to a Valsalva maneuver). A spontaneous orbital hemorrhage almost always occurs in the superior subperiosteal space. It should be allowed to resorb unless there is associated visual compromise, in which case urgent drainage is indicated. Also see the section Orbital Compartment Syndrome in Chapter 6.

Neural Tumors

The neural tumors that may involve the orbit include optic nerve gliomas, neurofibromas, meningiomas, and schwannomas.

Optic Nerve Glioma

Optic nerve gliomas are uncommon, usually benign tumors that occur predominantly in children in the first decade of life (Fig 5-8). The chief clinical feature is gradual, painless, unilateral axial proptosis associated with vision loss and an afferent pupillary defect. Other ocular findings may include optic atrophy, optic nerve head swelling, nystagmus, and strabismus. The chiasm is involved in roughly half of cases of optic nerve glioma. Intracranial involvement may be associated with intracranial hypertension as well as decreased function of the hypothalamus and pituitary gland. Up to half of optic nerve gliomas are associated with neurofibromatosis (NF). In patients with NF, the

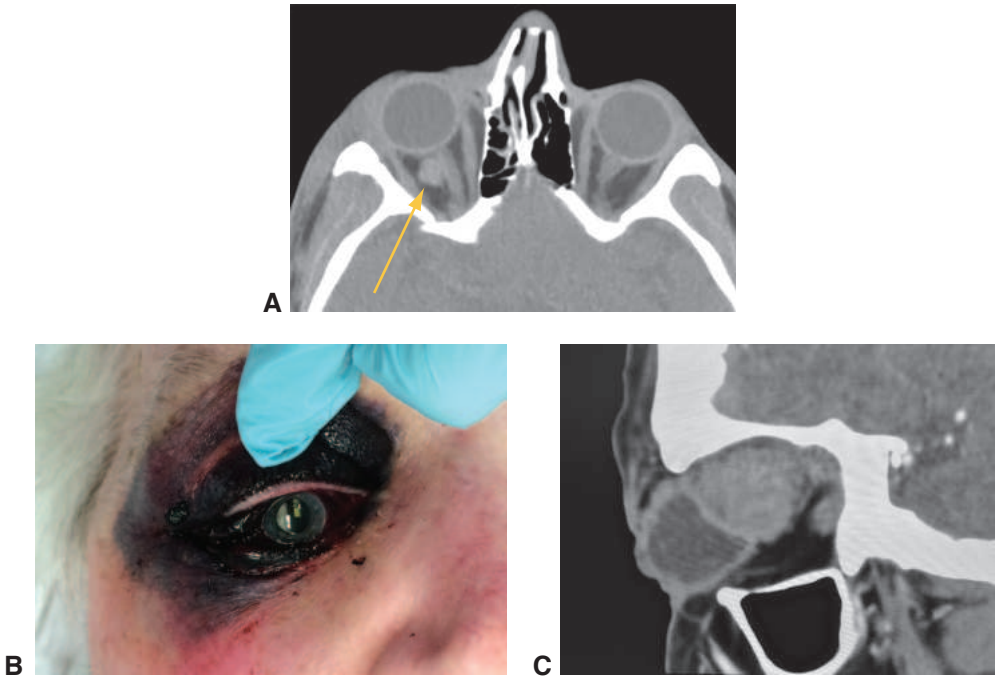

Figure 5-7 Orbital hemorrhage. **A,** CT scan shows an intraconal orbital hemorrhage *(arrow)* associated with a zygomaticomaxillary complex fracture. **B–C,** Orbital compartment syndrome from hemorrhage associated with disseminated intravascular coagulation from metastatic prostate cancer to the orbit. *(Part A courtesy of Bobby S. Korn, MD, PhD.; parts B and C courtesy of Cat N. Burkat, MD.)*

gliomas often proliferate in the subarachnoid space, while those that occur in patients without NF usually expand within the optic nerve substance without invading the dura mater.

Optic nerve gliomas can usually be diagnosed by means of orbital imaging. CT and MRI typically show fusiform enlargement of the optic nerve, often with stereotypical kinking of the nerve (Fig 5-9). MRI may also show cystic degeneration, if present, and may be more accurate than CT in defining the extent of an optic canal lesion and intracranial disease.

Because neuroimaging is frequently diagnostic, it is usually unnecessary to perform a biopsy of a suspected lesion. Moreover, obtaining tissue from an appropriate site may be challenging: biopsy of the optic nerve itself may produce additional loss of visual field or vision, while a specimen from a too-peripheral portion of the nerve may inadvertently capture reactive meningeal hyperplasia adjacent to the glioma and lead to a misdiagnosis of fibrous meningioma. Gross pathology of resected tumors reveals a smooth, fusiform intradural lesion. On microscopic examination, benign tumors in children are considered to be juvenile pilocytic (hairlike) astrocytomas. Other histologic findings include arachnoid hyperplasia, mucosubstance, and Rosenthal fibers (see the discussion of the pathologic features of glioma in BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors*).

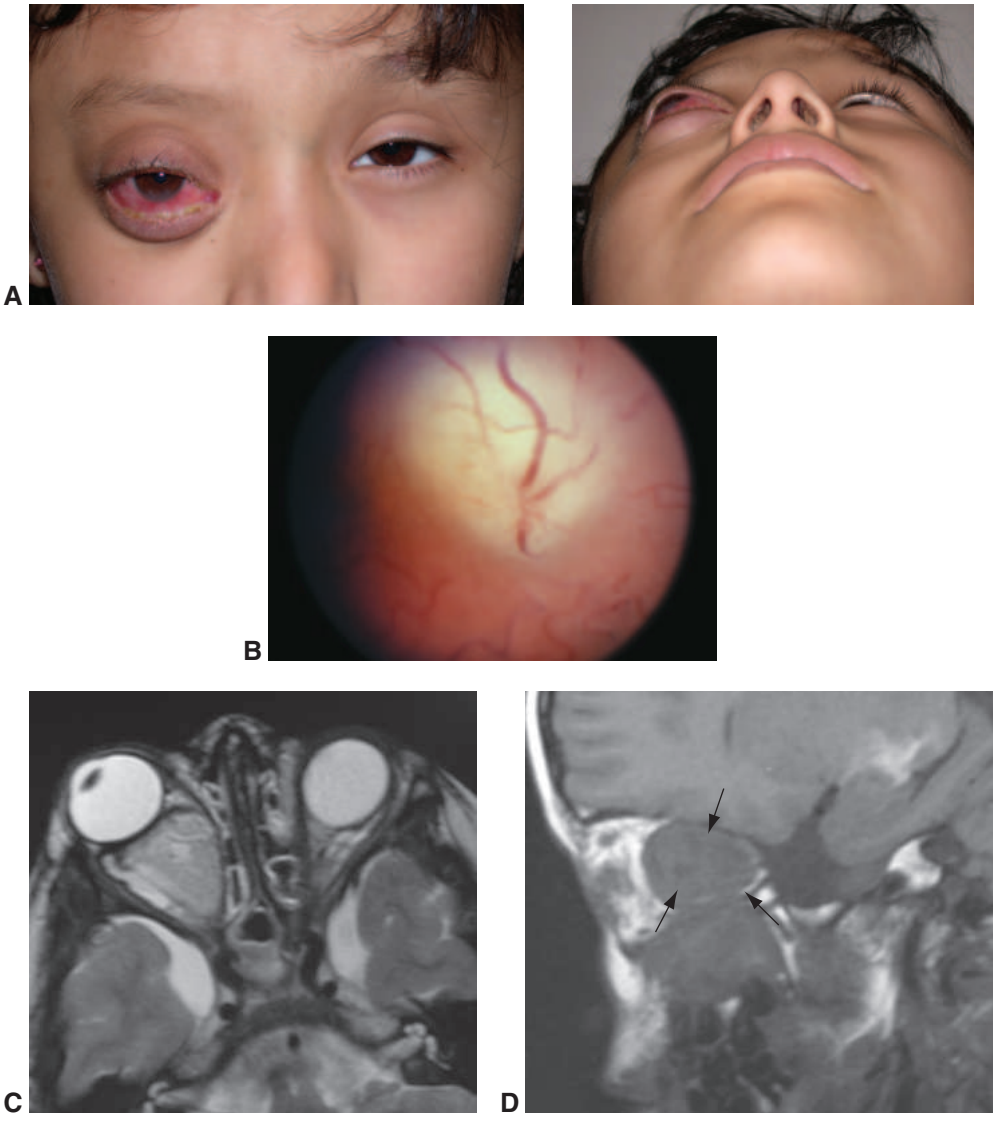

Figure 5-8 Optic nerve glioma. **A,** Right optic nerve glioma. The patient has severe proptosis with exposure and light perception vision. **B,** Funduscopic view. Note swollen optic nerve head with obscured margins. **C,** T2-weighted axial MRI shows glioma extending into the optic canal. **D,** Sagittal MRI shows a heterogeneous mass *(arrows)* in the apex of the orbit. *(Parts A, C, and D courtesy of Raymond Douglas, MD; part B courtesy of Roger A. Dailey, MD.)*

Malignant optic nerve gliomas (glioblastomas) are very rare and tend to affect adult males. Initial signs and symptoms of malignant gliomas include severe retro-orbital pain, unilateral or bilateral vision loss, and, typically, massive swelling and hemorrhage of the optic nerve head (pallor may also be observed with posterior lesions). Despite treatment, including high-dose radiotherapy and chemotherapy, these tumors usually result in death within 6–12 months.

Avey, MD.)*

Management

The treatment of nonmalignant optic nerve gliomas is controversial. Although most cases remain stable or progress very slowly, leading some to consider them benign hamartomas, the occasional case behaves aggressively. There are rare reports of spontaneous regression of optic nerve and visual pathway gliomas. Cystic enlargement of the lesions leading to sudden vision loss can occur even without true cellular growth. A treatment plan must be carefully individualized for each patient and comanaged with other specialists, including those in the fields of low vision and social services. Factors affecting therapeutic decisions include the tumor's growth characteristics, extent of optic nerve and chiasmal involvement as determined by clinical and radiographic evaluation, vision in the involved and uninvolved eyes, presence or absence of concomitant neurologic or systemic disease, and history of previous treatment. The following options may be considered.

Observation only Presumed optic nerve glioma, particularly with good vision on the involved side, may be carefully followed if the radiographic evidence is characteristic of this type of tumor and the glioma is confined to the orbit. Because visual function does not directly correlate with glioma size or growth, follow-up should include precise measurements of optic nerve function in addition to serial imaging studies. Many patients maintain good vision and never require surgery.

Surgical excision To obtain tumor-free surgical margins, the surgeon uses a transcranial approach. Surgical excision of a tumor confined to the orbit may also be considered if it causes severe proptosis with corneal exposure or unacceptable cosmesis. Removal through an intracranial approach may also be indicated at the time of initial diagnosis or after a short period of observation if the tumor involves the prechiasmal intracranial portion of the optic nerve. Complete excision is possible if the tumor ends 2–3 mm anterior to the chiasm.

Chemotherapy Combination chemotherapy using dactinomycin, vincristine, etoposide, and other agents has been reported to be effective in patients with progressive chiasmal-hypothalamic gliomas. Chemotherapy may delay the need for radiation therapy and thus reduce deleterious effects on long-term intellectual development and endocrine function in children. However, chemotherapy may carry long-term risks of blood-borne cancers.

Radiation therapy Radiation therapy is typically considered if the tumor cannot be resected (usually the case for lesions of the chiasm or optic tract) and if symptoms, particularly neurologic, progress after chemotherapy. It may also be considered after surgical excision if reliable radiographic studies document subsequent growth of the tumor in the chiasm or if chiasmal and optic tract involvement is extensive. Because of potentially debilitating adverse effects (including intellectual disability, growth retardation, secondary tumors, and malignant transformation within the radiation field), radiation is generally reserved as a last resort for children who have not completed growth and development.

See additional discussion of optic nerve glioma in BCSC Section 5, *Neuro-Ophthalmology.*

Neurofibroma

Neurofibromas are tumors composed chiefly of proliferating Schwann cells within the nerve sheaths. Axons, endoneural fibroblasts, and mucin are also noted on histologic examination. *Plexiform neurofibromas* consist of diffuse proliferations of Schwann cells within nerve sheaths, and they usually occur in cases of neurofibromatosis 1 (NF1). They are well-vascularized infiltrative lesions, making complete surgical excision difficult. *Discrete neurofibromas* are less common than the plexiform type and can usually be excised without recurrence. In either instance, surgery is limited to tumors that compromise vision or produce disfigurement.

Neurofibromatosis 1

Patients with neurofibromas are evaluated for neurofibromatosis. Also known as *von Recklinghausen disease,* NF1 is inherited through an autosomal dominant gene with incomplete penetrance. Because NF1 is characterized by the presence of hamartomas involving the skin, eye, central nervous system, and viscera, it is classified as a phakomatosis. NF1 is the most common phakomatous disorder; its significant orbital features include plexiform neurofibromas of the lateral aspect of the upper eyelid that result in an S-shaped contour of the eyelid margin (Fig 5-10), pulsatile proptosis (Video 5-1) secondary to sphenoid bone aplasia, and optic nerve glioma. See BCSC Section 6, *Pediatric Ophthalmology and Strabismus,* for further discussion of neurofibromatosis and other phakomatoses.

Meningioma

Meningiomas are invasive tumors that arise from the arachnoid villi.

Orbital meningiomas usually originate intracranially along the sphenoid wing, with secondary extension through the bone into the orbit (Fig 5-11), the superior orbital fissure, or the optic canal; or they may arise primarily in the orbital portion of the optic nerve sheath. Ophthalmic manifestations are related to the location of the primary tumor. Meningiomas that arise near the sella and optic nerve cause early visual field defects and optic nerve edema or optic atrophy. Tumors that arise near the pterion (the posterior end of the parietosphenoid fissure, at the lateral portion of the sphenoid bone) often produce a mass in the temporal fossa and may be associated with proptosis or nonaxial displacement of the globe (Fig 5-11A, B). Eyelid edema (especially of the lower eyelid) and chemosis are common. Interestingly, although primary optic nerve sheath meningiomas can, in rare cases, produce axial proptosis with preserved vision, depending on their anatomic location, some meningiomas can cause early profound vision loss without any proptosis.

Sphenoid wing meningiomas produce hyperostosis of the involved bone (Fig 5-11C) and hyperplasia of associated soft tissues. Contrast-enhanced MRI helps define the extent of meningiomas along the dura (Fig 5-11D). The presence of a *dural tail* (reactive thickening of the dura adjacent to the meningioma) helps distinguish a meningioma from fibrous dysplasia.

Primary orbital meningiomas usually originate in the arachnoid of the optic nerve sheath. They occur most commonly in women in their third or fourth decade of life. Symptoms usually include a gradual, painless, unilateral loss of vision. Examination typically shows decreased vision and a relative afferent pupillary defect. Proptosis and ophthalmoplegia may also be present. The optic nerve head may appear normal, atrophic, or swollen, and tortuous vessels may be visible (Fig 5-12A, B). Occasionally, optic nerve sheath meningiomas are present bilaterally, or meningiomas occur ectopically in the orbit; these are associated with neurofibromatosis.

Optic nerve sheath meningiomas can usually be diagnosed by means of imaging characteristics. Both CT and MRI show diffuse tubular enlargement of the optic nerve with contrast enhancement (Fig 5-12C, D). In some cases, CT can show calcification within the meningioma, referred to as *tram-tracking*. MRI reveals a fine pattern of enhancing striations emanating from the lesion in a longitudinal fashion. These striations represent the infiltrative nature of what otherwise appears to be an encapsulated lesion. As with sphenoid wing meningiomas, dural extension through the optic canal into the intracranial space can be seen on MRI.

Figure 5-11 Sphenoid wing meningioma. **A,** Patient demonstrates right temporal fullness *(arrow).* **B,** Worm's eye view shows right proptosis. CT **(C)** and MRI **(D)** demonstrate hyperostosis of the sphenoid bone *(green arrow)* from the associated meningioma *(red arrow).* *(Courtesy of Bobby S. Korn, MD, PhD.)*

Malignant meningioma is rare and results in rapid tumor growth that is not responsive to surgical resection, radiotherapy, or chemotherapy. On histologic examination, malignant meningiomas are indistinguishable from the more common benign group.

Management

Sphenoid wing meningioma Sphenoid wing meningiomas are typically observed until they cause functional deficits, such as profound proptosis, compressive optic neuropathy, motility impairment, or cerebral edema. Treatment includes resection of the tumor through a combined approach to the intracranial and orbital component. Complete surgical resection is not always practical because of tumor extension beyond the surgical field. Rather, the goal of surgery is to reverse the volume-induced compressive effects of the lesion. Postoperative radiotherapy may be used to reduce the risk of further growth and spread of the residual tumor, or patients can be followed clinically and with serial MRI scans.

Optic nerve sheath meningioma Treatment of optic nerve sheath meningiomas in the orbit also must be individualized. Both the amount of vision loss and the presence of intracranial extension are important factors in treatment planning. Observation is indicated if vision is minimally affected and no intracranial extension is present. If the tumor is confined to the orbit and vision loss is significant or progressive, radiation therapy should be considered. Fractionated stereotactic radiotherapy often results in stabilization or improvement of visual function. If the patient is observed or treated with radiation, periodic MRI examination is used to carefully monitor for possible posterior or intracranial

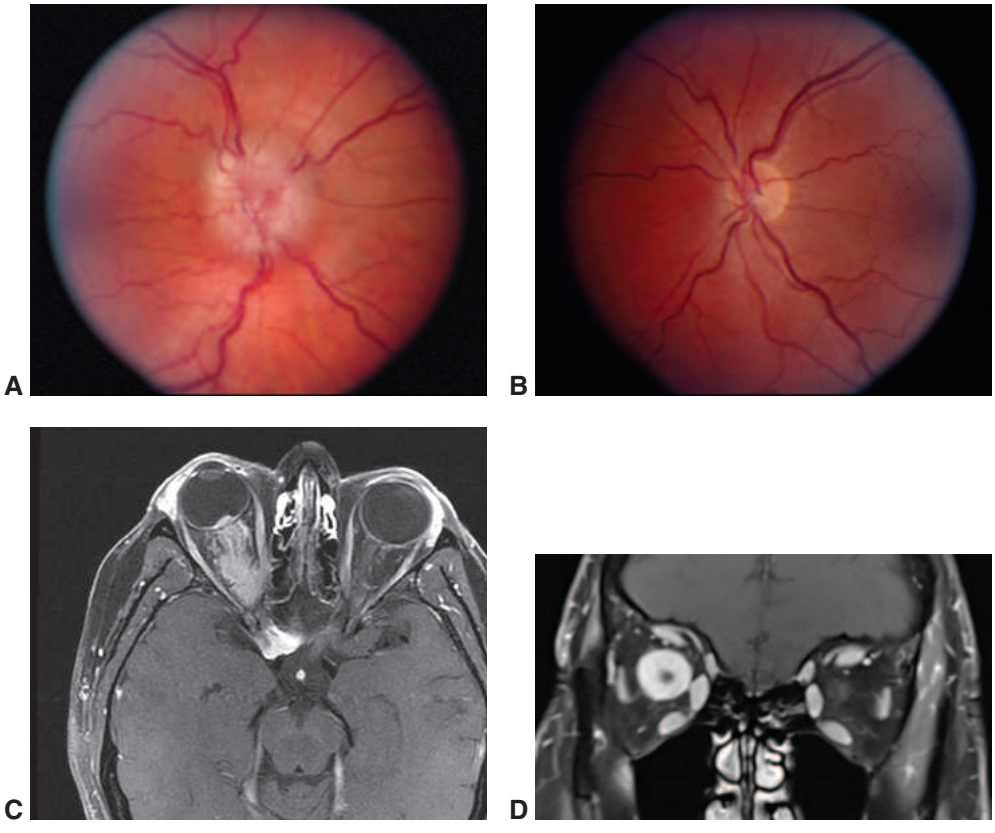

Figure 5-12 Optic nerve sheath meningioma. **A,** Swollen right optic nerve with tortuous arteries and dilated veins. **B,** Normal left optic nerve. extension. With rare exceptions, attempts to surgically excise optic nerve sheath meningiomas result in irreversible vision loss due to compromise of the optic nerve blood supply. Thus, surgery is reserved for patients with severe vision loss and profound proptosis. In such cases, the optic nerve is excised with the tumor, from the back of the globe to the chiasm, if preoperative MRI suggests that complete resection is possible.

Schwannoma

Schwannomas, sometimes known as *neurilemomas,* are proliferations of Schwann cells that are encapsulated by perineurium. These tumors have a characteristic biphasic pattern of solid areas with nuclear palisading *(Antoni A pattern)* and myxoid areas *(Antoni B pattern).* These tumors are usually well encapsulated and can be excised with relative ease. Hypercellular schwannomas sometimes recur even after what was thought to be complete removal, but they seldom undergo malignant transformation.

Mesenchymal Tumors

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common primary orbital malignancy of childhood. The average age of onset is 5–7 years. The classic clinical picture is that of a child with sudden onset and rapid progression of unilateral proptosis. However, patients in their early teens may experience a less dramatic course, with gradually progressive proptosis developing over weeks to more than a month. There is often a marked adnexal response, with edema and discoloration of the eyelids. Ptosis and strabismus may also be present. A mass may be palpable, particularly in the superonasal quadrant of the eyelid, and it may cause proptosis if sufficiently large (Fig 5-13A, B). However, the tumor may be retrobulbar, may involve any quadrant of the orbit, and may in rare cases arise from the conjunctiva. If the patient has an unrelated history of trauma to the orbital area, this can lead to a delay in diagnosis and treatment.

If a rhabdomyosarcoma is suspected, the workup should proceed urgently. CT and MRI can be used to define the location and extent of the tumor (Fig 5-13C). A biopsy should be performed, usually through an anterior orbitotomy approach (Fig 5-13D). If the lesion is focal and has a pseudocapsule, it may be possible to completely remove the tumor. If this is not practical, nonsurgical treatment can be considered: there is some indication that the smaller the volume of residual tumor, the more effective is the combination of adjuvant radiation and chemotherapy in achieving a cure. In diffusely infiltrating rhabdomyosarcoma,

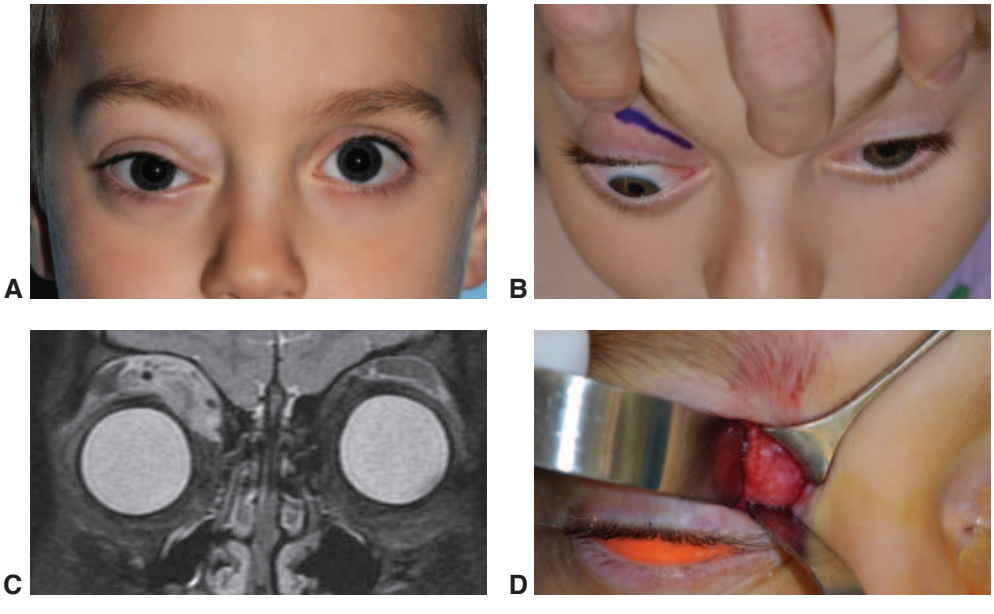

Figure 5-13 Orbital rhabdomyosarcoma. Lesion presenting as a right upper eyelid mass causing inferolateral globe displacement **(A)** and proptosis **(B)**. **C,** T2-weighted MRI shows a mass in the right superonasal quadrant. **D,** Anterior orbitotomy through the upper eyelid provided tissue for pathologic analysis. *(Courtesy of Bobby S. Korn, MD, PhD.)*

a large biopsy specimen should be obtained to provide adequate tissue for frozen sections, permanent light-microscopy sections, electron microscopy, and immunohistochemistry. Cross-striations are often not visible on light microscopy and may be more readily apparent on electron microscopy.

The physician should palpate the cervical and preauricular lymph nodes of a patient with orbital rhabdomyosarcoma to evaluate for regional metastases. Chest radiography, bone marrow aspiration and biopsy, and lumbar puncture should be performed to search for more distant metastases. Sampling of the bone marrow and cerebrospinal fluid is best performed, if possible, with the patient under anesthesia at the time of the initial orbital biopsy.

Rhabdomyosarcomas arise from undifferentiated pluripotent mesenchymal elements in the orbital soft tissues, not from the extraocular muscles. They may be grouped into the following 4 categories:

- *Embryonal.* This is by far the most common type, accounting for more than 80% of cases. The embryonal form is typically found in the superonasal quadrant of the orbit. The tumor is composed of loose fascicles of undifferentiated spindle cells, only a minority of which show cross-striations in immature rhabdomyosarcomas on trichrome staining. Embryonal rhabdomyosarcomas are associated with a good 5-year survival rate (94%).
- *Alveolar.* This form typically occurs in the inferior orbit and accounts for 9% of orbital rhabdomyosarcomas. The tumor displays regular compartments composed of fibrovascular strands in which rounded rhabdomyoblasts either line up along the connective tissue strands or float freely in the alveolar spaces. This is the most malignant form of rhabdomyosarcoma; the 5-year survival rate for the alveolar subtype is 65%.
- *Pleomorphic.* Pleomorphic rhabdomyosarcoma is the least common and best-differentiated form overall and most frequently affects young adults. In this type, many of the cells are straplike or rounded, and cross-striations are easily visualized with trichrome stain. The pleomorphic variety has the best prognosis (5-year survival rate of 97%).
- *Botryoid.* This rare variant of embryonal rhabdomyosarcoma appears grapelike. It is not found in the orbit as a primary tumor; rather, the botryoid variant occurs only through secondary extension from the paranasal sinuses or the conjunctiva. Rhabdomyosarcoma that occurs in the head and neck region outside the orbit, including the sinus cavities, has a lower 5-year survival rate (50%–71%) than rhabdomyosarcoma in the orbit, likely because tumors in the head and neck region produce fewer signs and symptoms.

Crist W, Gehan EA, Ragab AH, et al. The Third Intergroup Rhabdomyosarcoma Study. *J Clin Oncol.* 1995;13(3):610–630.

Management

Before 1965, the standard treatment for orbital rhabdomyosarcoma was orbital exenteration, and the survival rate was poor. After 1965, radiation therapy and systemic chemotherapy became the mainstays of primary treatment, based on the guidelines set forth by the Intergroup Rhabdomyosarcoma Study Group. Exenteration is reserved for recurrent cases. The

total dose of local radiation varies from 4500 to 6000 cGy, given over a period of 6 weeks. The goal of systemic chemotherapy is to eliminate microscopic cellular metastases. With radiation and chemotherapy, survival rates are better than 90% if the orbital tumor has not invaded or extended beyond the bony orbital walls. Adverse effects of radiation are common in children and include cataract, radiation dermatitis, and bony hypoplasia if orbital development has not been completed.

Miscellaneous Mesenchymal Tumors

Tumors of fibrous connective tissue, cartilage, and bone are uncommon lesions that may involve the orbit. It is likely that a number of these mesenchymal tumors were classified incorrectly before the availability of immunohistochemical staining, which has allowed them to be differentiated accurately.

Fibrous histiocytoma (Fig 5-14 A–E) is the most common of these tumors. Characteristically, it is very firm and displaces normal structures. Both fibroblastic and histiocytic cells in a storiform (matlike) pattern are found in these locally aggressive tumors. Less than 10% have metastatic potential. This tumor is sometimes difficult to distinguish, clinically and histologically, from a solitary fibrous tumor.

A solitary fibrous tumor (Fig 5-15) is composed of spindle-shaped cells that are strongly positive for CD34 and STAT 6 on immunohistochemical studies. These

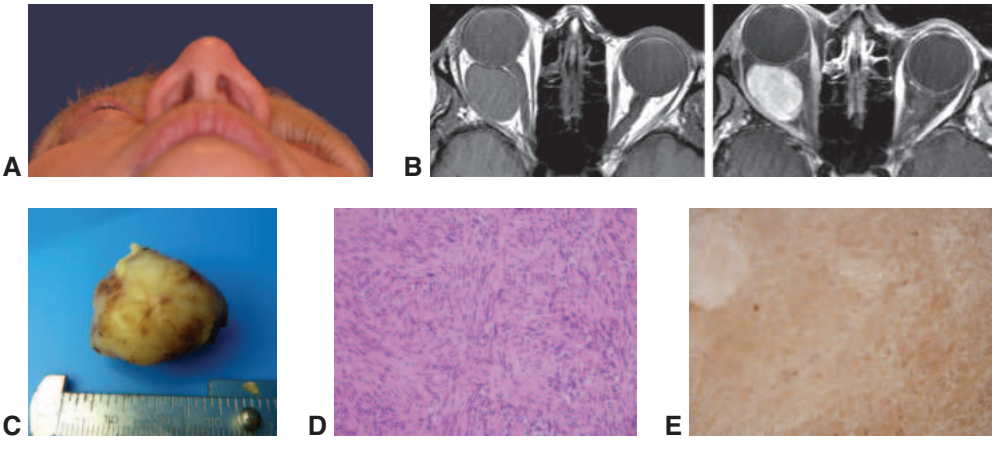

Figure 5-14 Fibrous histiocytoma. **A,** Lesion presenting in a patient as a right globe proptosis. **B,** T1-weighted MRI imaging shows a hypointense retrobulbar mass abutting the optic nerve; it enhances with contrast. **C,** Complete excision of mass. **D,** Pathologic analysis with hematoxylin-eosin (H&E) staining, which shows a storiform pattern. **E,** Vimentin staining. *(Courtesy of Cat N. lesions, some of which were previously termed *hemangiopericytomas,* are uncommon, encapsulated, hypervascular, and hypercellular; they often appear in midlife. They can occur anywhere in the orbit, and they may recur, undergo malignant degeneration, or metastasize if incompletely excised. They may resemble cavernous venous malformations on both CT and MRI; however, solitary fibrous tumors are characterized by rapid enhancement and early washout of contrast agent. On histologic examination, these tumors are unique in that microscopically "benign" lesions may recur and metastasize, whereas microscopically "malignant" lesions may remain localized. Treatment consists of complete excision.

Fibrous dysplasia (Fig 5-16) is a benign developmental disorder of bone that may involve a single region or be polyostotic. CT shows hyperostotic bone, and MRI shows the lack of dural enhancement that distinguishes this condition from meningioma. When associated with cutaneous pigmentation and endocrine disorders, the condition is known as *McCune-Albright syndrome.* Resection or debulking is performed when the lesion causes disfigurement or vision loss due to stricture of the optic canal.

Osteomas (Fig 5-17) are benign tumors that can involve any of the periorbital sinuses. CT scans show dense hyperostosis with well-defined margins. The lesions can produce proptosis, compressive optic neuropathy, and orbital cellulitis secondary to obstructive sinusitis. Most are incidental, slow-growing lesions that require no treatment. Complete excision is advised when the tumor is symptomatic.

Malignant mesenchymal tumors such as *liposarcoma, fibrosarcoma, chondrosarcoma,* and *osteosarcoma* rarely appear in the orbit. When chondrosarcomas and osteosarcomas are

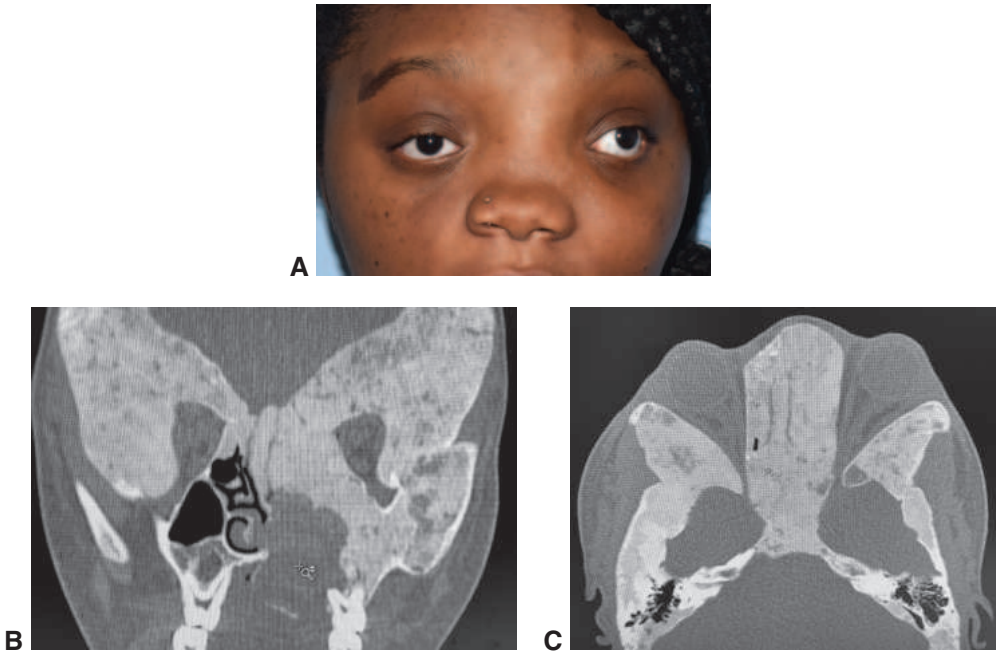

Figure 5-16 Fibrous dysplasia/McCune-Albright syndrome. **A,** Facial asymmetry. **B–C,** Coronal and axial CT scans demonstrate characteristic hyperostosis of involved facial bones. *(Courtesy of William R. Katowitz, MD.)*

present, they usually destroy normal bone and demonstrate characteristic calcifications in radiographs and CT scans. Children with a history of bilateral retinoblastoma are at higher risk for osteosarcoma, chondrosarcoma, or fibrosarcoma, even if they have not been treated with therapeutic radiation.

Lymphoproliferative Disorders

Lymphoid Hyperplasia and Lymphoma

Lymphoproliferative lesions of the ocular adnexa constitute a heterogeneous group of neoplasms that are defined by clinical, histologic, immunologic, molecular, and genetic characteristics. Lymphoproliferative neoplasms account for more than 20% of all orbital tumors.

The vast majority of orbital lymphoproliferative lesions are non-Hodgkin lymphoma (NHL). In the United States, the incidence of NHL in all anatomic sites has been increasing, and it is one of the most common malignancies affecting the orbit. Workers with long-term exposure to bioactive solvents and reagents are at increased risk for NHL, as are older adults and individuals with chronic autoimmune diseases.

Identification and classification of lymphoproliferative disorders

Non-Hodgkin lymphoma encompasses a heterogeneous group of malignancies and includes many subtypes. The Revised European-American Lymphoma Classification applies immunophenotypic and genetic features to identify distinct clinicopathologic NHL entities, including extranodal sites such as the orbit. The World Health Organization's classification elaborates on this approach. Orbital extranodal disease appears to represent a biological continuum and behaves unpredictably. By molecular genetic studies, approximately 90% of orbital lymphoproliferative disease is monoclonal, and 10% is polyclonal; however, both types of lesions may involve prior, concurrent, or future systemic spread. Approximately 20%–30% of periocular lymphoproliferative lesions have a history of previous or concomitant systemic disease, and an additional 30% develop it over 5 years. The risk of systemic disease remains elevated for decades after the original lesion is diagnosed, regardless of the initial lesion's location in the orbit or its clonality.

The risk of having or developing systemic NHL is lowest for conjunctival lesions, greater for orbital lesions, and highest for lesions that arise in the eyelid. Lymphoid lesions that develop in the fossa of the lacrimal gland may carry a greater risk of systemic disease than those that occur elsewhere in the orbit. Bilateral periocular involvement markedly increases the risk of systemic disease, but such involvement is not definitive evidence of systemic disease.

Most orbital lymphomas (98%) are derived from B cells. T-cell lymphoma is rare and more lethal. B-cell lymphoma is divided into Hodgkin and non-Hodgkin tumors, with the former rarely metastasizing to the orbit. The 4 most common types of orbital lymphomas are presented in order below:

- *Extranodal marginal zone B-cell lymphoma, EMZL* (also known as *mucosa-associated lymphoid tissue,* or *MALT*). EMZL accounts for approximately 57% of orbital lymphomas and is associated with upregulation of nuclear factor κB (NF-κB). NF-κB is a major transcription factor that is involved in the innate and adaptive immunologic system. Inactivating variants in the *A20* gene, an inhibitor of NF-κB, have also been noted in cases of EMZL. In the gastrointestinal tract, EMZL has been associated with *Helicobacter pylori* in gastric lymphomas in which antimicrobial therapy has been

effective. EMZL has been weakly associated with chlamydial infection, and antibiotic therapy is generally not recommended.

EMZLs are low-grade malignancies, and 5%–15% of cases undergo spontaneous remission. However, systemic disease develops in at least 50% of patients within 10 years, and 15%–20% of cases undergo histologic transformation to a higher-grade lesion, usually of a large cell type. Such transformation usually occurs after several years and is not related to therapy.

- *Diffuse large B-cell lymphoma (DLBCL)* comprises 15% of orbital lymphomas. DLBCL also occurs in various intraocular compartments. It has been associated with multiple chromosomal translocations and alterations in the *BCL2, BCL6, MYC, EZH2,* and *MEF2B* genes.
- *Follicular lymphoma (FL)*. This type of lymphoma represents a low-grade lesion with follicular centers and is the third-most-common orbital lymphoma (11%). The most common translocation associated with FL is t(14;18)(q32;q21), which results in high levels of the antiapoptotic protein BCL2.
- *Mantle cell lymphoma (MCL)* accounts for 8% of orbital lymphomas. Translocation t(11;14)(q13;q32), which is associated with overexpression of CCND1 (Cyclin D-1), is classically seen with MCL.

Clinical presentation

The typical lymphoproliferative lesion presents as a gradually progressive, painless mass that results in proptosis, a visible periocular mass, or ptosis (Fig 5-18). These tumors are often located anteriorly in the orbit or beneath the conjunctiva, where they may show the typical salmon-patch appearance (Fig 5-19). Lymphoproliferative lesions, whether benign or malignant, usually mold to surrounding orbital structures rather than invading them; consequently, disturbances of extraocular motility or visual function are unusual. Reactive lymphoid hyperplasia and low-grade lymphomas often have a history of slow expansion over a period of months to years. Regional lymph nodes should be palpated during the clinical examination.

Diagnosis

Orbital imaging reveals a characteristic puttylike molding of the tumor to normal structures (see Fig 5-18B). Bone erosion or infiltration is usually not seen except with high-grade malignant lymphomas. Up to 50% of orbital lymphoproliferative lesions arise in the fossa of the lacrimal gland. Lymphomas in the retrobulbar fat may appear more infiltrative. Approximately 17% of orbital lymphoid lesions occur bilaterally, but this does not necessarily indicate the presence of extraorbital disease.

For all lymphoproliferative lesions, an open biopsy is preferred to obtain an adequate tissue specimen. A portion of the tissue should be placed in a suitable fixative for light microscopy, and the majority should be sent fresh to a molecular diagnostics laboratory for possible flow cytometry, immunohistochemistry, and genomic analysis. Fine-needle

aspiration biopsy may establish all but the morphologic characteristics of the lesion. Conjunctival biopsy for follicular conjunctivitis can sometimes reveal a lymphoproliferative lesion.

Both reactive lymphoid hyperplasia and malignant lymphoma are hypercellular proliferations with sparse or absent stromal components. Light microscopy may reveal

a histologic continuum from reactive lymphoid hyperplasia to low-grade lymphoma to higher-grade malignancy; it may not by itself adequately characterize a given lesion. In such cases, immunopathology and molecular diagnostic studies aid in further categorization.

Malignant lymphomas are thought to represent clonal expansions of abnormal precursor cells. Immunologic identification of lymphocyte cell-surface markers can classify tumors as containing B cells or T cells. Specific monoclonal antibodies directed against surface light-chain immunoglobulins are used to determine whether the cells represent monoclonal (ie, malignant) proliferations.

Genetic analysis has shown that most lymphoproliferative lesions that appear to be immunologically polyclonal actually harbor small monoclonal proliferations of B lymphocytes. However, the finding of monoclonality, by either immunophenotype or molecular genetics, does not predict which tumors will ultimately result in systemic disease.

Management

Because there is considerable overlap among the various lymphoproliferative lesions in terms of clinical presentation and behavior, all patients with hypercellular lymphoid lesions (whether monoclonal or polyclonal) should be examined by an oncologist. Depending on the histologic type of the lesion, the examination may include a general physical examination, a complete blood count, a bone marrow biopsy, CT and/or MRI imaging, a positron emission tomography scan, and serum immunoprotein electrophoresis. The patient should be reexamined periodically because systemic lymphoma may develop many years after the occurrence of an isolated orbital lymphoid neoplasm.

For EMZL and FL, radiotherapy usually results in good outcomes, with 10-year survival rates of 92% and 71%, respectively. DLBCL and MCL have a poorer prognosis, with 10-year survival rates of 41% and 32%, respectively. Treatment of non-EMZL more often involves chemotherapy and immunomodulation in addition to radiotherapy. The optimal dose of radiation has not been established, with published amounts ranging from 20–40 Gy in fractionated doses. A surgical cure is usually not possible because of the infiltrative nature of lymphoid tumors. Alternative treatments include targeted therapies such as rituximab for CD20-positive lymphomas.

The management of low-grade lymphoid lesions that have already undergone systemic dissemination is somewhat controversial because indolent lymphomas are generally refractory to chemotherapy and are associated with long-term survival, even if untreated. Many oncologists take a watchful-waiting approach and treat only symptomatic disease.

Yen MT, Bilyk JR, Wladis EJ, Bradley EA, Mawn LA. Treatments for ocular adnexal lymphoma. A report by the American Academy of Ophthalmology. *Ophthalmology*. 2018;125(1):127–136.

Plasma Cell Tumors

Lesions composed predominantly of mature plasma cells may be plasmacytomas or localized plasma cell–rich masses. Multiple myeloma should be ruled out, particularly if there is bone destruction or any immaturity or mitotic activity of the plasmacytic elements. Some lesions are composed of lymphocytes and lymphoplasmacytoid cells and demonstrate the combined

properties of both lymphocytes and plasma cells. Plasma cell tumors display the same spectrum of clinical involvement as do lymphoproliferative lesions but are much less common.

Histiocytic Disorders

Langerhans cell histiocytosis (formerly called *histiocytosis X*) is a collection of rare disorders of the mononuclear phagocytic system (Fig 5-20). These disorders are thought to result from abnormal immune regulation. All subtypes are characterized by an accumulation of proliferating dendritic histiocytes. The disease occurs most commonly in children, with a peak

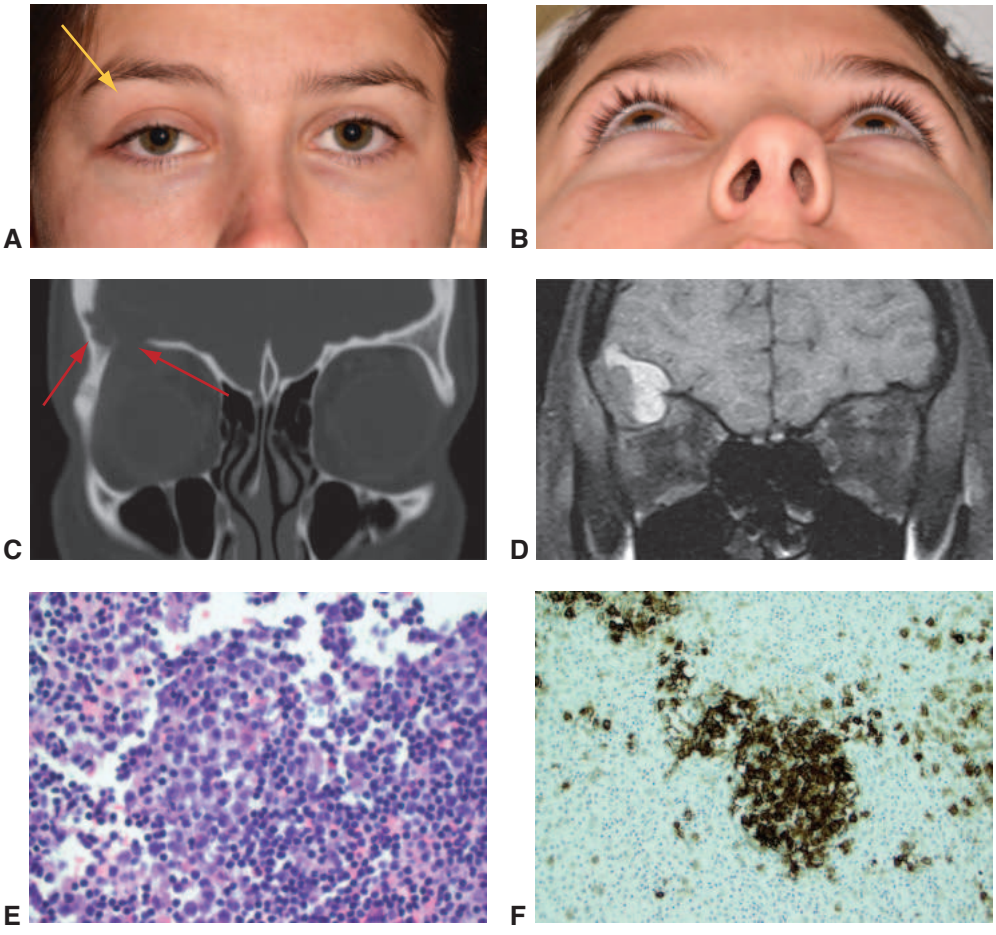

Figure 5-20 Langerhans cell histiocytosis. **A,** 18-year-old woman with ptosis of the right upper eyelid, fullness *(arrow),* and inferior globe displacement. **B,** Worm's-eye view demonstrates 2 mm of proptosis of the right eye. **C,** Coronal CT scan shows lytic erosion of the superotemporal orbital bone *(arrows).* **D,** Coronal MRI scan shows the soft tissue with an intracranial and intraorbital component. **E,** H&E stain of the lesion demonstrates numerous foamy histiocytes. **F,** Immunohistochemistry with CD1a antibody confirms the diagnosis of Langerhans cell histiocytosis. *(Courtesy of Bobby S. Korn, MD, PhD.)*

incidence between 5 and 10 years of age, and it varies in severity, from benign lesions with spontaneous resolution to chronic dissemination that results in death. Older names representing the various manifestations of histiocytic disorders *(eosinophilic granuloma of bone, Hand-Schüller-Christian disease,* and *Letterer-Siwe disease)* are being replaced by the terms *unifocal* and *multifocal eosinophilic granuloma of bone* and *diffuse soft tissue histiocytosis.*

If sufficiently large, the mass may cause proptosis (Fig 5-20A, B). Younger children more often present with significant overlying soft-tissue inflammation; they are also more likely to have multifocal or systemic involvement. Even if the initial workup shows no evidence of systemic dissemination, younger patients require regular observation for possible development of multiorgan disease. The most frequent presentation in the orbit is a lytic defect best noted on CT imaging (Fig 5-20C), which usually affects the superotemporal orbit or sphenoid wing and causes relapsing episodes of orbital inflammation; it is often initially misdiagnosed as infectious orbital cellulitis. MRI imaging aids in visualization of the soft-tissue component (Fig 5-20D). Histopathology shows foamy histiocytes with abundant eosinophilic cytoplasm and irregular nuclei that are immunoreactive for antibodies against CD1a (see Fig 5-20E, F).

Management

Histiocytic disorders have a reported survival rate of only 50% in patients who are younger than 2 years at presentation; if the disease develops after age 2, the survival rate rises to 87%. Treatment of localized orbital disease consists of confirmatory biopsy with debulking, which may be followed by intralesional steroid injection or low-dose radiation therapy. Spontaneous remission has also been reported. Although destruction of the orbital bone may be extensive at the time of presentation, the bone usually reossifies completely. Children with systemic disease are treated with aggressive chemotherapy.

Esmaili N, Harris GJ. Langerhans cell histiocytosis of the orbit: spectrum of disease and risk of central nervous system sequelae in unifocal cases. *Ophthalmic Plast Reconstr Surg.* 2016;32(1):28–34.

Xanthogranuloma

Adult xanthogranuloma of the adnexa and orbit is often associated with systemic manifestations. These manifestations are the basis for classification into the following 4 syndromes, presented in their order of frequency.

- *Necrobiotic xanthogranuloma (NBX)* (Fig 5-21). This disorder is characterized by the presence of subcutaneous lesions in the eyelids and anterior orbit; lesions may also occur throughout the body. Although skin lesions are seen in all 4 syndromes, those occurring in NBX have a propensity for ulceration and fibrosis. Systemic findings frequently include paraproteinemia and multiple myeloma.
- *Adult-onset asthma with periocular xanthogranuloma (AAPOX)* (Fig 5-22). This syndrome includes periocular xanthogranuloma, asthma, lymphadenopathy, and, often, increased levels of immunoglobulin G.
- *Erdheim-Chester disease (ECD)* (Fig 5-23). The most devastating of the adult xanthogranulomas, ECD is characterized by dense, progressive, recalcitrant fibrosclerosis

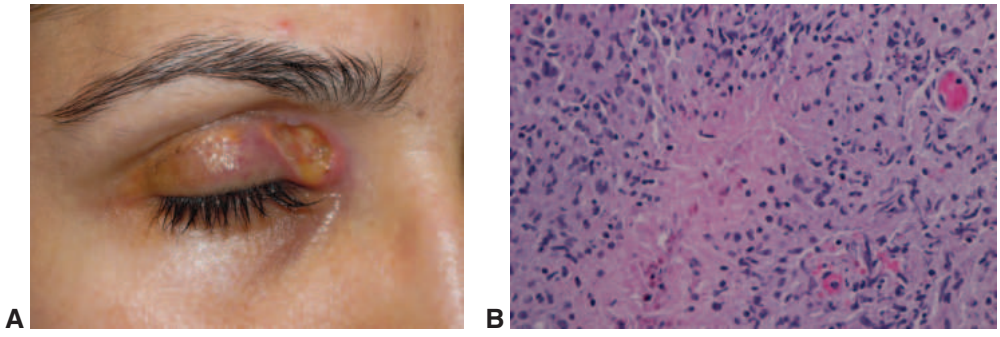

Figure 5-21 Necrobiotic xanthogranuloma. **A,** 56-year-old woman with progressive ulcerative yellow plaque of the right upper eyelid, associated with scleritis. **B,** H&E stain consistent with lymphocytes and foamy histiocytes within pink areas of necrobiosis (collagen degeneration). *(Courtesy of Rona Z. Burkat, MD.)*

of the orbit and internal organs, including the mediastinum; the pericardium; and the pleural, perinephric, and retroperitoneal spaces. Whereas xanthogranuloma of the orbit and adnexa tends to be anterior in NBX, AAPOX, and AOX, it is often diffuse in ECD and leads to vision loss. Bone involvement is common, and the syndrome often is fatal, despite treatment with aggressive therapies.

T1-weighted MRI axial **(A)** and coronal **(B)** views show diffuse infiltration of a mass in the intraconal space bilaterally. **C,** X-ray of the femur shows lytic bone lesions *(arrows)*. **D,** H&E stain of the lesion demonstrates numerous foamy histiocytes. *(Courtesy of Don O. Kikkawa, MD.)*

- *Adult-onset xanthogranuloma (AOX)*. AOX is an isolated xanthogranulomatous lesion without systemic involvement. *Juvenile xanthogranuloma* is a separate non-Langerhans histiocytic disorder that occurs as a self-limited, corticosteroid-sensitive, and usually focal subcutaneous disease of childhood. See BCSC Section 6, *Pediatric Ophthalmology and Strabismus*, for additional discussion of juvenile xanthogranuloma.

Lacrimal Gland Tumors

Most lacrimal gland masses represent nonspecific inflammation *(dacryoadenitis)*. They present with acute inflammatory signs and usually respond to anti-inflammatory medication (see the section Nonspecific Orbital Inflammation in Chapter 4). Of those lacrimal gland tumefactions not presenting with inflammatory signs and symptoms, the majority are lymphoproliferative disorders (discussed previously). Up to 50% of orbital lymphomas develop in the fossa of the lacrimal gland. Only a minority of lacrimal fossa lesions are epithelial neoplasms of the lacrimal gland.

Imaging is helpful in evaluating lesions in the lacrimal gland region. Inflammatory and lymphoid proliferations in the lacrimal gland tend to cause it to expand diffusely and appear elongated, whereas epithelial neoplasms tend to appear as isolated globular masses. Inflammatory and lymphoproliferative lesions usually mold around the globe, but epithelial neoplasms tend to displace and indent it. The bone of the lacrimal fossa is remodeled in response to a slowly growing benign epithelial lesion of the lacrimal gland; however, lymphoproliferative lesions typically do not cause bony changes.

Epithelial Tumors of the Lacrimal Gland

Approximately 50% of epithelial tumors are benign mixed tumors *(pleomorphic adenomas),* and about 50% are carcinomas. Approximately half of the carcinomas are adenoid cystic carcinomas, and the remainder are malignant mixed tumors, primary adenocarcinomas, mucoepidermoid carcinomas, and squamous carcinomas.

Pleomorphic adenoma

Pleomorphic adenoma is the most common epithelial tumor of the lacrimal gland. This tumor usually occurs in adults during the fourth or fifth decade of life and affects slightly more men than women. Patients present with a progressive, painless inferior and medial displacement of the globe with axial proptosis (Fig 5-24A). Symptoms usually persist for many months prior to diagnosis.

A firm, lobular mass may be palpated near the superolateral orbital rim, and orbital imaging often reveals enlargement or expansion of the fossa of the lacrimal gland. On imaging, the lesion appears well circumscribed but may have a slightly nodular configuration (Fig 5-24B, C).

Microscopically, pleomorphic adenomas have a varied cellular structure consisting primarily of a proliferation of benign epithelial cells and a stroma composed of spindle-shaped cells with occasional cartilaginous, mucinous, or even osteoid degeneration or metaplasia. Because of this variability, the term *benign mixed tumor* is sometimes used. The lesion is circumscribed by a pseudocapsule.

Management Treatment is complete removal of the pleomorphic adenoma with its pseudocapsule and a surrounding margin of orbital tissue (Fig 5-24D). Surgery should be performed without a preliminary biopsy: in an early study, the recurrence rate was 32% when the capsule was incised for direct biopsy. In recurrences, the risk of malignant degeneration into carcinoma ex pleomorphic adenoma is 10% per decade.

Adenoid cystic carcinoma

Adenoid cystic carcinoma (ACC) is the most common malignant epithelial tumor of the lacrimal gland. This highly malignant carcinoma may cause pain because of perineural invasion and bone destruction. The relatively rapid course, with a history of generally less than 1 year, and early onset of pain help differentiate ACC from pleomorphic adenoma, which is painless and characteristically exhibits progressive proptosis for more than a year. In ACC, the tumor usually extends into the posterior orbit because of its capacity to infiltrate and its lack of true encapsulation.

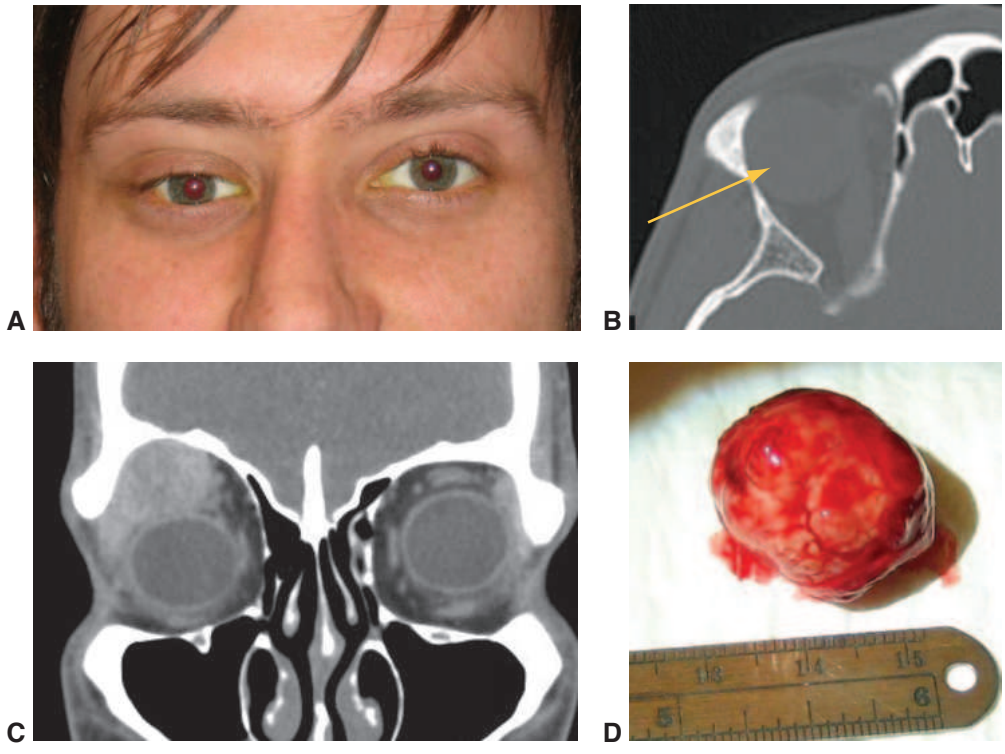

Figure 5-24 Pleomorphic adenoma. **A,** Adult male with inferomedial displacement of the right globe. **B,** Axial CT scan shows a well-circumscribed mass *(arrow)* in the superotemporal orbit with no lytic erosion of the bone. **C,** Coronal CT shows the mass displacing the right globe inferiorly and medially. **D,** The mass was completely removed with the pseudocapsule intact through a lateral orbitotomy approach. *(Courtesy of Eric A. Steele, MD.)*

Microscopically, this tumor is composed of deceptively benign-appearing cells that grow in tubules, solid nests, or a Swiss-cheese pattern. The basaloid morphology is associated with worse survival than the cribriform variant. Infiltration of the orbital tissues, including perineural invasion, is often seen in microscopic sections.

Malignant mixed tumor

These lesions are histologically similar to pleomorphic adenomas (benign mixed tumors), but they have areas of malignant change, usually poorly differentiated adenocarcinomas. They typically arise from a long-standing primary pleomorphic adenoma or from a pleomorphic adenoma that has recurred after initial incomplete excision or violation of the pseudocapsule (see the section "Pleomorphic adenoma"). An increase in growth rate is a hallmark of malignant degeneration.

Management of malignant lacrimal gland tumors

Suspicion of a malignant lacrimal gland tumor warrants biopsy with permanent histologic confirmation. Traditional treatment is centered around orbital exenteration or radical orbitectomy followed by radiotherapy; however, the survival benefit of exenteration remains

unproven. Other treatment strategies include neoadjuvant intra-arterial chemotherapy followed by exenteration or eye-sparing surgery followed by radiation (typically proton) therapy. Despite these measures, ascending perineural extension often develops, usually leading to death from intracranial extension or, less commonly, from systemic metastases (managed by local resection) a decade or more after the initial presentation.

Woo KI, Kim YD, Sa HS, Esmaeli B. Current treatment of lacrimal gland carcinoma. *Curr Opin Ophthalmol.* 2016;27(5):449–456.

Nonepithelial Tumors of the Lacrimal Gland

The vast majority of nonepithelial lesions of the lacrimal gland represent lymphoid proliferation or inflammations, discussed earlier in this chapter and in Chapter 4 of this volume.

Benign lymphocytic infiltrates may be seen in patients, particularly women, who have bilateral swelling of the lacrimal gland, which produces a dry eye syndrome. This condition can occur insidiously or following a symptomatic episode of lacrimal gland inflammation. The enlargement of the lacrimal glands may not be clinically apparent. Biopsy specimens of the affected glands show a spectrum of lymphocytic infiltration, from scattered patches of lymphocytes to lymphocytic replacement of the lacrimal gland parenchyma with preservation of the inner duct cells, which are surrounded by proliferating myoepithelial cells *(epimyoepithelial islands).* This combination of lymphocytes and epimyoepithelial islands has led some to designate this manifestation as a lymphoepithelial lesion. Some patients with lymphocytic infiltrates may also have systemic rheumatoid arthritis and, therefore, have classic Sjögren syndrome. These lesions may develop into low-grade B-cell lymphoma (see the section Lymphoproliferative Disorders). Associated dry eye symptoms may improve with the use of topical cyclosporine.

Secondary Orbital Conditions

Secondary orbital tumors are those that extend into the orbit from contiguous structures, including the globe, the eyelids, the lacrimal drainage system, the sinuses, and the brain.

Globe and Eyelid Origin

Tumors and inflammations from within the eye (especially from choroidal melanomas and retinoblastomas) or from the eyelid (eg, sebaceous gland carcinoma, squamous cell carcinoma, and basal cell carcinoma) can invade the orbit. Primary eyelid tumors are discussed in Chapter 10. Retinoblastoma, choroidal melanoma, and other ocular neoplasms are covered in BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors,* and Section 6, *Pediatric Ophthalmology and Strabismus.*

Yin VT, Pfeiffer ML, Esmaeli B. Targeted therapy for orbital and periocular basal cell carcinoma and squamous cell carcinoma. *Ophthalmic Plast Reconstr Surg.* 2013;29(2):87–92.

Sinus Disease Affecting the Orbit

Tumors from the nose or the paranasal sinuses may secondarily invade the orbit; proptosis, globe displacement, and strabismus are common. The diagnosis is made by imaging, which is ordered to include the base of the sinuses for proper evaluation.

Mucoceles and *mucopyoceles* of the sinuses (Fig 5-25) are cystic structures with pseudostratified ciliated columnar (respiratory) epithelium resulting from obstruction of the sinus excretory ducts. These lesions may invade the orbit by expansion and erosion of the bones of the orbital walls and cause globe displacement. In the case of mucoceles, the cysts are usually filled with thick mucoid secretions; in the case of mucopyoceles, they are filled with pus. Most mucoceles arise from the frontal and/or ethmoid sinuses. Surgical treatment includes evacuation of the mucocele and reestablishment of drainage of the affected sinus or obliteration of the sinus by mucosal stripping and packing with bone or fat.

Silent sinus syndrome is another orbital condition that results from sinus outflow pathology (Fig 5-26). Chronic subclinical sinusitis presumably causes thinning of the bones of the maxillary sinus, leading to collapse of the orbital floor and subsequent enophthalmos. This collapse may occur in association with a recent significant change in atmospheric pressure (eg, during airplane travel or scuba diving). Upper eyelid ptosis, deepening of the superior sulcus, and, occasionally, diplopia may occur. Treatment includes restoration of maxillary

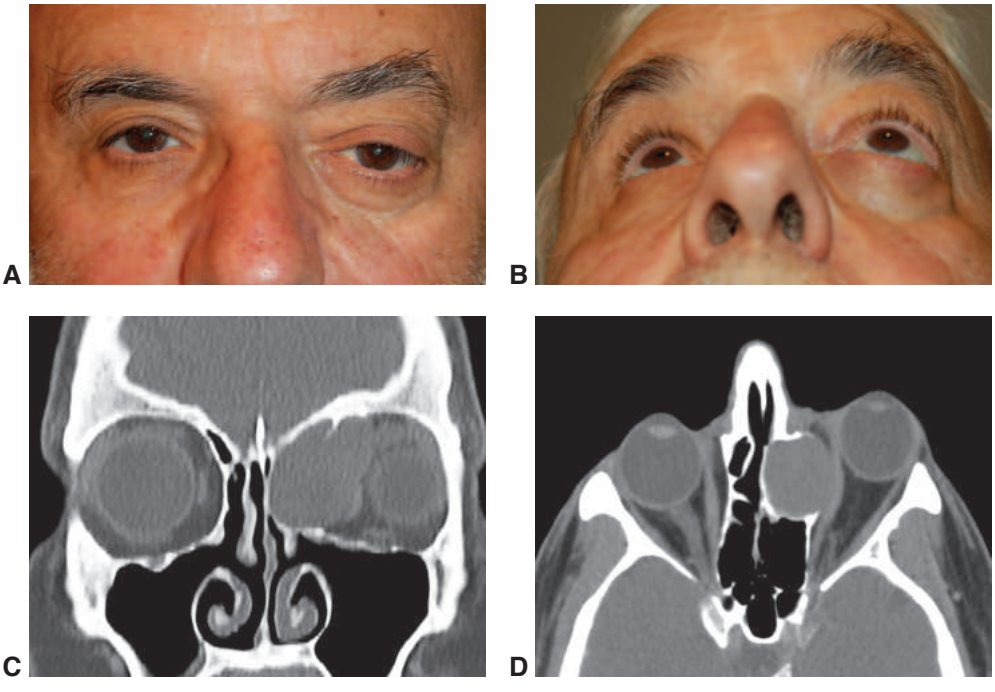

Figure 5-25 Mucocele. **A,** Inferior and lateral displacement of the left globe. **B,** Worm's-eye view demonstrates left proptosis. Coronal **(C)** and axial **(D)** CT scans show a frontoethmoidal mucocele expanding laterally into the orbit. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Korn, MD, PhD; part C courtesy of Rona Z. Silkiss, MD; part D courtesy of Cat N. Burkat, MD.)*

sinus aeration and reconstruction of the orbital floor. The entrapped maxillary sinus secretions are often sterile in nature.

Squamous cell carcinoma and *adenocarcinoma* of the sinuses may secondarily invade the orbit (Fig 5-27). These malignancies usually arise in the maxillary sinuses, followed by the nasopharynx or the oropharynx. Nasal obstruction, epistaxis, and epiphora may be associated with the growth of such tumors. Treatment is usually a combination of surgical excision and radiation therapy and often includes exenteration if the periorbita is traversed by tumor.

Nonepithelial tumors that can invade the orbit from the sinuses, nose, and facial bones include a wide variety of benign and malignant lesions. Among the most common are osteomas, fibrous dysplasia, and miscellaneous sarcomas.

Metastatic Tumors

Metastatic Tumors in Children

In children, distant tumors metastasize to the orbit more frequently than to the globe (in contrast to adults, who more frequently have metastases to the choroid). Tumors that can metastasize to the orbit in children include Burkitt lymphoma, leukemia, neuroblastoma, Ewing sarcoma, and Wilms tumor (nephroblastoma).

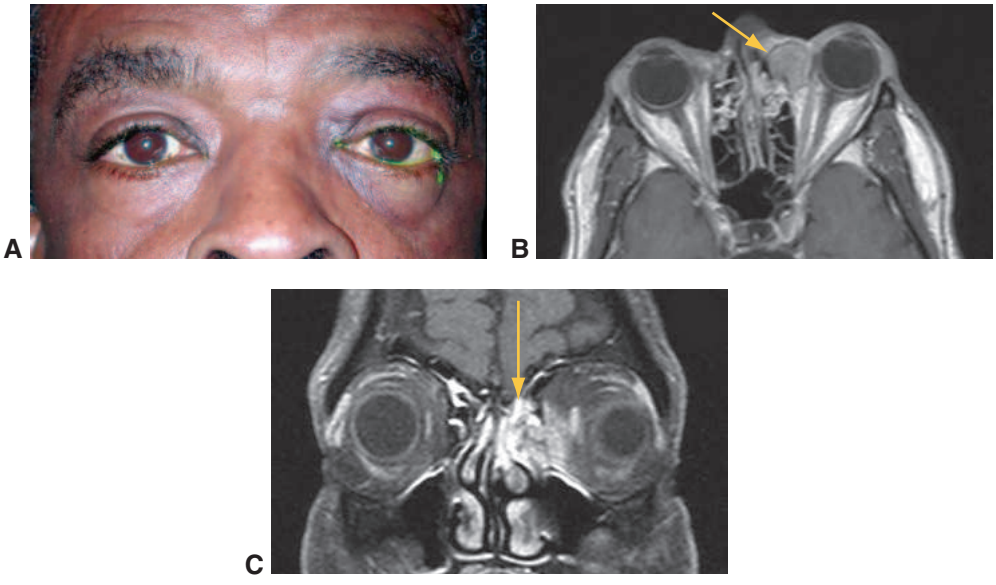

Figure 5-27 Ethmoid sinus squamous cell carcinoma. **A,** Photograph shows fullness of the medial canthal area overlying the mass. Axial **(B)** and coronal **(C)** T1-weighted MRI with gadolinium contrast reveals a mass in the ethmoid sinus eroding into the medial orbit *(arrows).* *(Courtesy of Julian D. Perry, MD, and Alexander D. Blandford, MD.)*

Leukemia

In advanced stages, leukemia may produce unilateral or bilateral proptosis. *Acute lymphoblastic leukemia* is the type of leukemia most likely to metastasize to the orbit. A primary leukemic orbital mass, called *granulocytic sarcoma* or *chloroma,* is a rare variant of myelogenous leukemia. Least common are metastases to the subarachnoid space of the optic nerve. These cases present with sudden vision loss and swelling of the optic nerve. They constitute an emergency and are treated with orbital radiotherapy.

Typically, orbital lesions present before blood or bone marrow demonstrate signs of leukemia, which almost invariably follow within several months. Special stains for cytoplasmic esterase in the cells (Leder stain) indicate that they are granulocytic precursor cells. Chances for survival are improved if chemotherapy is instituted before the discovery of leukemic involvement in bone marrow or peripheral blood.

Neuroblastoma

Metastatic orbital neuroblastoma occurs in 10%–20% of cases and typically produces an abrupt ecchymotic proptosis that may be bilateral. A deposition of blood in the eyelids may lead to the mistaken impression of injury (Fig 5-28). Horner syndrome may also be evident in some cases. Commonly, bone destruction is apparent on CT, particularly in the lateral orbital wall or sphenoid marrow. Metastases typically occur late in the course of the disease, when the primary tumor can be detected readily in the abdomen, mediastinum, or neck. Treatment consists primarily of chemotherapy; radiotherapy is reserved for cases of impending vision loss due to compressive optic neuropathy. The survival rate of neuroblastoma is

related to the patient's age at diagnosis. Patients diagnosed before 1 year of age have a significantly better prognosis (a 5-year survival of 85%) than children diagnosed after 1 year of age (5-year survival rate of 36%). Unfortunately, the average age of presentation of patients with orbital metastases is over 2 years of age. Congenital neuroblastoma of the cervical ganglia may produce an ipsilateral Horner syndrome with heterochromia.

Metastatic Tumors in Adults

Although virtually any cancer of the internal organs, hematopoietic system, or skin can metastasize to the orbit, most orbital metastases derive from lung, breast, and prostate tumors. The presence of pain, proptosis, inflammation, bone destruction, and early ophthalmoplegia suggests the possibility of metastatic carcinoma.

Some 75% of patients have a history of a known primary tumor, but orbital metastasis is the presenting sign of cancer in 25% of patients. The extraocular muscles are frequently involved because of their abundant blood supply. The second most common site is the bone marrow space of the sphenoid bone because of the relatively high volume of low-flow blood in this area (Fig 5-29). Lytic destruction of this part of the lateral orbital wall is highly suggestive of metastatic disease. Elevation of serum carcinoembryonic antigen levels also may suggest a metastatic process. Fine-needle aspiration biopsy can be performed in the office and may obviate the need for orbitotomy and open biopsy.

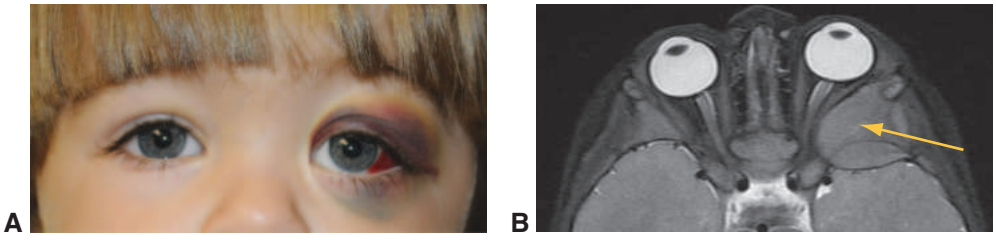

Figure 5-28 Metastatic neuroblastoma. **A,** Child with metastatic left orbital neuroblastoma. **B,** T2-weighted MRI shows a large infiltrating lesion of the left sphenoid wing extending into the orbital soft tissues and the temporal fossa *(arrow)*. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Couch, MD.)*

Breast carcinoma

The most common primary source of orbital metastases in women is breast cancer. Metastases may occur many years after the breast lesion has been removed; thus, the history should always include inquiries about previous cancer surgery. Breast metastasis to the orbit can elicit a fibrous response that causes enophthalmos and, possibly, restriction of ocular motility (Fig 5-30).

Some patients with breast cancer respond favorably to hormone therapy. This response usually correlates with the presence of estrogen and other hormone receptors in the tumor tissue. Estrogen receptor assay results from orbital metastases may differ from those of the primary lesion; thus, orbital tissue studies should include this assay. Hormone therapy is most likely to help patients whose tumors are receptor positive.

Bronchogenic carcinoma

The most frequent origin of orbital metastasis in men is bronchogenic carcinoma. The primary lesion may be quite small, and CT of suspicious lung lesions may be performed in patients suspected of having orbital metastases.

Prostate carcinoma

Metastatic prostate carcinoma can produce a clinical picture resembling that of acute nonspecific orbital inflammation (see Fig 5-29). Typically, an osteoblastic bone lesion is identified on imaging.

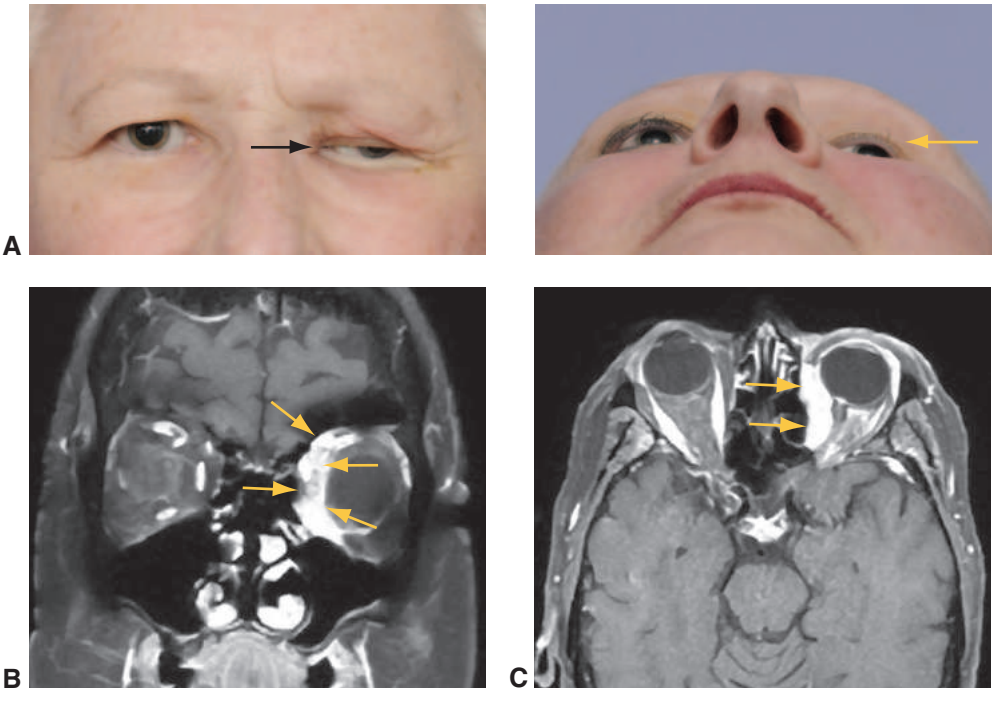

Figure 5-30 Metastatic breast carcinoma. **A,** Left enophthalmos *(arrows)* secondary to breast carcinoma metastasis to the orbit. Coronal **(B)** and axial **(C)** MRI images show medial infiltration of the orbit *(arrows)*. *(Courtesy of Hakan Demirci, MD.)*

Management of Orbital Metastases

The treatment of metastatic tumors of the orbit is usually palliative, consisting of local radiation therapy. Some metastatic tumors, such as carcinoids and renal cell carcinomas, may be candidates for wide excision of the orbital lesion because patients may survive for many years following resection of isolated metastases. Consultation with the patient's oncologist is important for identifying candidates who might benefit from wide excision.

CHAPTER 6

Orbital Trauma

This chapter includes related videos. Go to www.aao.org/bcscvideo_section07 or scan the QR codes in the text to acccess this content.

Highlights

- Orbital trauma is amongst the most common emergency department consultations and is often accompanied by trauma of the facial bones and soft tissue.
- Additional injuries that may be observed in the setting of orbital trauma include orbital hemorrhage, retained foreign body, and optic neuropathy.
- Ophthalmic manifestations of orbital trauma may include decreased vision, intraocular injury, strabismus, and eyelid or globe malposition.
- A complete ophthalmic examination should be performed on all patients who have sustained orbital trauma.
- Polycarbonate lenses should be encouraged for all patients in high-risk situations or occupations and routinely encouraged in all monocular patients.

Orbital Floor Fractures

Direct fractures of the orbital floor can extend from fractures of the inferior orbital rim, whereas indirect fractures of the orbital floor are not associated with fractures of the rim. Indications for repair of both fracture types are similar.

It is thought that orbital floor fractures are caused by 1 of 2 mechanisms or a combination of them. According to the hydraulic mechanism theory, blunt trauma rapidly occludes the orbital aperture, resulting in increased intraorbital pressure. This pressure causes the orbital bones to break or "blow out" at their weakest point along the posterior medial part of the floor, which comprises the maxillary bone. By contrast, according to the buckling mechanism theory, a striking object causes deformation of the inferior rim, resulting in forces that are transmitted to and focused on the orbital floor, resulting in a blowout fracture. Regardless of the mechanism, orbital contents may prolapse through the fracture into the maxillary sinus and become entrapped.

The diagnosis of a blowout fracture of the orbital floor is suggested by the patient's history, physical examination, and orbital imaging studies. There is often a history of the orbital aperture being struck by an object that is larger than its diameter (eg, a ball, an automobile dashboard, or a fist). An orbital blowout fracture should be suspected in any

patient who has received a periorbital blow forceful enough to cause ecchymosis. Physical examination typically reveals the following:

- *Eyelid signs.* Ecchymosis and edema of the eyelids may be present, but external signs of injury can be absent *(white-eyed blowout fracture).*
- *Diplopia with limitation of upgaze, downgaze, or both.* Limited vertical movement of the globe on attempted supraduction, with vertical diplopia and pain in the inferior orbit, can be consistent with tethering of the inferior rectus muscle or its adjacent septa in the fracture, especially in cases of pediatric orbital trauma. However, orbital edema and/or hemorrhage is a more likely cause of diplopia in the acute posttraumatic period and can take weeks to months to completely resolve. Less commonly, damage to the extraocular muscles or their innervation can result in significant limitation of both horizontal and vertical eye movements. If extraocular muscle tethering is present, a *forced duction test (traction test)* will show restriction of passive movement of the eye. This test can be performed with the instillation of anesthetic eyedrops followed by application of a cotton pledget of topical anesthetic in the inferior cul-de-sac for several minutes. Using toothed forceps, the examiner engages the insertion of the inferior rectus muscle through the conjunctiva and attempts to rotate the globe gently up and down. This test may be uncomfortable for a conscious patient and may be deferred to the time of surgery, when the patient is under anesthesia. Another characteristic finding of inferior rectus incarceration (or "entrapment") is an increase in intraocular pressure (IOP) with upgaze.
- *Enophthalmos and hypoglobus.* These findings can occur with large fractures in which the orbital soft tissues prolapse into the maxillary sinus. If associated with the orbital floor fracture, a medial wall fracture may significantly contribute to enophthalmos because of the prolapse of orbital tissues into both the ethmoid and maxillary sinuses. Enophthalmos may be masked by orbital edema immediately following injury and may become more apparent as edema subsides.
- *Hypoesthesia in the distribution of the infraorbital nerve.* Trauma to the orbital floor or maxilla may injure the infraorbital nerve as it traverses within the infraorbital canal of the orbital floor, or as it exits the foramen below the orbital rim. Numbness or paresthesia may extend to the associated cheek, nasal ala, upper lip, and upper teeth.
- *Emphysema of the orbit and eyelids.* Any fracture that extends into a sinus may allow air to escape into the subcutaneous tissues and is commonly associated with fractures of the medial orbital wall. Patients with fractures are advised to avoid nose blowing to prevent orbital emphysema which may feel like "bubble wrap in the skin."
- *Entrapment.* This clinical syndrome involves pinched extraocular muscles within fracture segments and results in extreme limitation in extraocular movement. This muscle incarceration can induce a vagal response that may cause nausea, vomiting, and oculocardiac reflex with bradycardia.

In patients with orbital floor fractures, vision loss can result from globe trauma, injury to the optic nerve, or increased orbital pressure that causes an *orbital compartment syndrome* (discussed later in this chapter, in the section Orbital Compartment Syndrome).

An orbital hemorrhage should be suspected if loss of vision is associated with proptosis and increased IOP. Injuries to the globe and ocular adnexa may also be present.

Management

Thin-cut orbital computed tomography (CT) with coronal, axial, and sagittal views enables evaluation of the fracture size and extraocular muscle relationships, providing information that may help predict enophthalmos and muscle entrapment. However, despite the publication of multiple studies suggesting neuroimaging criteria for extraocular muscle entrapment, restrictive strabismus related to blowout fracture remains a clinical diagnosis.

Most orbital floor fractures do not require surgical intervention. Patients may be observed from weeks to months to allow edema and orbital hemorrhage to subside. Oral steroids (1 mg/kg per day for the first 7 days) decrease edema and may help hasten the decision of whether surgery for diplopia is necessary.

An indication for urgent repair is the clinical syndrome of entrapment, which most commonly occurs in pediatric patients (Fig 6-1). In these younger patients, the bone bends and cracks, rather than breaks off, and in the process, the inferior rectus muscle is more likely to become tightly ensnared within a trapdoor segment. In these patients, vertical

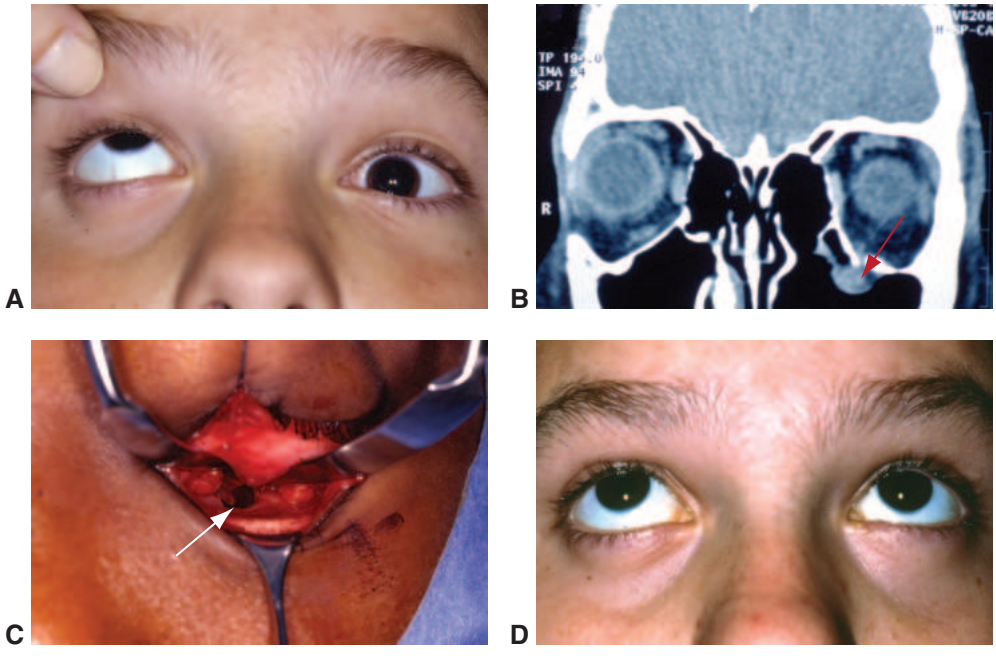

Figure 6-1 Orbital floor fracture. **A,** Teenaged patient following blunt trauma to the eye and orbit. With attempted upgaze, there is limited supraduction of the left eye. Note the lack of ecchymosis of the left side (white-eyed blowout fracture). **B,** Coronal computed tomography (CT) scan of the orbit shows a minimally displaced orbital floor fracture and inferior rectus muscle prolapsing into the maxillary sinus *(arrow)*. **C,** Intraoperative view of a similar case shows an orbital floor defect *(arrow)* enlarged surgically to release and extract inferior rectus muscle. **D,** In a photo taken 2 months postoperatively, the patient demonstrates resolution of upgaze limitation. *(Courtesy of John B. Holds, MD.)*

globe excursion is significantly limited (Video 6-1), and CT may reveal the inferior rectus muscle within the fracture site or an "absent" inferior rectus muscle within the orbit. Eye movement may stimulate the oculocardiac reflex (Video 6-2), causing pain, nausea, and bradycardia. Timely repair, with release of the entrapped muscle, should be undertaken in these cases. Time-sensitive repair may improve the final ocular motility by limiting muscle necrosis and subsequent fibrosis.

Otherwise, the indications and timing for surgery remain controversial. Currently, there are no prospective, randomized clinical trials to guide decision making, and recommendations are based on noncomparative, retrospective reports or case series. The following 3 criteria are suggested to define when surgery may be indicated:

- *Diplopia with limitation of upgaze and/or downgaze within 30° of the primary position; positive forced duction test; and radiologic confirmation of an orbital floor fracture.* These findings may indicate functional entrapment of tissues affecting the inferior rectus muscle. Diplopia will improve significantly over the course of the first several weeks to months as orbital edema and/or hemorrhage resolve and the entrapped tissues stretch. If the findings are still present after 2 weeks, some surgeons prefer to repair the fracture, whereas others prefer to continue observing until findings are no longer improving. As mentioned earlier, tight entrapment of the inferior rectus muscle with possible muscle ischemia is an indication for timely repair.
- *Enophthalmos that exceeds 2 mm and is cosmetically unacceptable to the patient.* Enophthalmos can be masked by orbital edema immediately after the injury and may delay recognition of the enophthalmos for weeks to months. Exophthalmometry measurements are taken at the initial evaluation and at subsequent visits to monitor for enophthalmos. Some surgeons believe that when significant enophthalmos is present within the first 2 weeks of a large orbital floor fracture, greater enophthalmos may ensue, and thus intervention is indicated. Others believe that late enophthalmos is rare, even in the case of large fractures, and thus longer observation is appropriate, with the patient ultimately deciding whether the degree of enophthalmos is aesthetically unacceptable.
- *Large fractures involving at least half of the orbital floor, particularly when associated with large medial wall fractures, as determined by CT.* Orbital fractures of this size may have a higher incidence of subsequent significant enophthalmos, and repair may be sought. However, studies have shown that it can be difficult to predict who will proceed to develop significant enophthalmos based on imaging alone.

Surgical management of orbital fractures

True entrapment with vasovagal symptoms and extreme extraocular muscle limitation requires timely repair. Otherwise, some surgeons prefer to proceed with the repair within 2 weeks of the initial trauma, believing that scar tissue formation and contracture of the prolapsed tissue make later correction of diplopia and/or enophthalmos difficult. Other surgeons prefer to observe the fracture to allow complete resolution of the orbital edema and/or hemorrhage and thereafter determine whether residual diplopia and/or aesthetically significant enophthalmos merits repair. Satisfactory correction of diplopia and enophthalmos is obtainable even if surgery is delayed or not performed/deferred.

The surgical approach to blowout fractures of the orbital floor is ideally performed through an inferior transconjunctival incision either with or without a lateral canthotomy and inferior cantholysis. In some cases, surgical exploration and fracture repair can be accomplished through lacerations around the fracture. The approaches through the lower eyelid have the following steps in common: elevation of the periorbita from the orbital floor, release of the prolapsed tissues from the fracture, and, usually, placement of an implant over the fracture to prevent recurrent adhesions and prolapse of the orbital tissues (Fig 6-2).

Orbital implants can be alloplastic (porous polyethylene, nylon foil, polytetrafluoroethylene, silicone sheet, or titanium mesh) or autogenous (split cranial bone, iliac crest bone, or fascia). Alloplastic implants combined with both synthetic and metallic components enable microplating and are an option for the management of large orbital floor and/or combined medial wall fractures. The harvesting of autologous grafts requires an additional operative site, and bone grafts are rarely indicated. Customized orbital implants made from either standardized skull anatomy or from the anatomy of the contralateral orbit may be useful in large fractures or revision repairs (Fig 6-3).

Couch, MD.)*

Delayed treatment of blowout fractures to correct persistent restrictive diplopia or cosmetically unacceptable enophthalmos may include exploration of the orbital floor to free prolapsed tissue and reposition it in the orbit. In late surgery for enophthalmos, placement of an implant to reposition the globe anteriorly and/or superiorly may be necessary. Other treatment options include strabismus surgery and procedures to camouflage the narrowed palpebral fissure and deep superior sulcus associated with enophthalmos.

Complications of blowout fracture surgery include decreased vision or blindness, persistent or new diplopia, undercorrection or overcorrection of enophthalmos, eyelid malposition (retraction, ectropion, or entropion), hypoesthesia of the infraorbital nerve, infection, early or late extrusion of the implant, lymphedema, delayed orbital hemorrhage around the implant, implant cyst, and damage to the lacrimal drainage system.

Other Orbital Fractures

Zygomatic Fractures

Zygomaticomaxillary complex (ZMC) fractures (Fig 6-4) are also referred to as *quadripod fractures* because the zygoma is usually fractured at 4 of its articulations with the adjacent bones: (1) frontozygomatic suture, (2) inferior orbital rim, (3) zygomatic arch, and (4) lateral wall of the maxillary sinus. ZMC fractures involve the orbital floor and lateral wall to

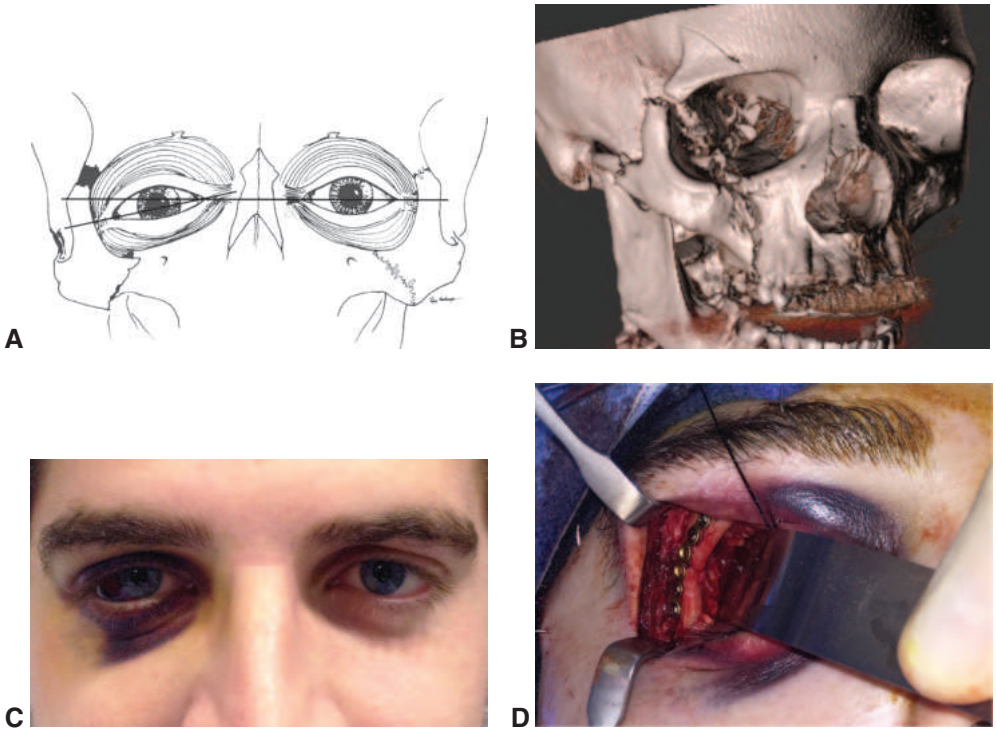

Figure 6-4 Zygomaticomaxillary complex (ZMC) fracture. **A,** ZMC, anterior view. Downward displacement of the globe and lateral canthus result from frontozygomatic separation and downward displacement of the zygoma and the floor of the orbit. **B,** 3D imaging of a right ZMC fracture with displacement of the zygomatic body. **C,** Globe ptosis and lateral canthal dystopia result from a depressed ZMC fracture. **D,** Intraoperative view shows rigid plate fixation of a supralateral orbital rim fracture that was performed in addition to fixation of the inferior rim and lateral maxillary buttress. *(Part A modified with permission from Converse JM, ed.* Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation. *2nd ed. Saunders; 1977:2. Part B courtesy of Steven M. Couch, MD, and parts C and D courtesy of M. Reza Vagefi, MD.)*

varying degrees. If the zygoma is not significantly displaced, treatment may not be necessary. ZMC fractures can cause globe displacement, lateral canthal dystopia, cosmetic deformity, diplopia, and trismus (limitation of mandibular opening) due to fracture impingement on the coronoid process of the mandible.

When treatment is indicated, the best results are obtained with open reduction of the fracture and rigid plate fixation (see Fig 6-4D). Exact realignment and stabilization of the lateral maxillary buttress and the lateral orbital wall are essential for accurate fracture reduction and can be achieved through a combination of eyelid and buccal sulcus incisions. If the lateral maxillary buttress is only mildly displaced, complete reduction and fixation can be accomplished through eyelid incisions.

Orbital Apex Fractures

Orbital apex fractures usually occur in association with other fractures of the face, orbit, or skull and may involve the optic canal, superior orbital fissure, and structures that pass

through them (Fig 6-5). Possible associated complications include traumatic optic neuropathy; cerebrospinal fluid leak; and carotid-cavernous fistula. Orbital CT may demonstrate evidence of direct optic nerve injury with a fracture at or adjacent to the optic canal.

Orbital Roof Fractures

Orbital roof fractures are usually caused by blunt trauma or missile injuries (see Fig 6-5). They are more common in young children, in whom the frontal sinus has yet to pneumatize. Because the ratio of the cranial vault to the midface is greater in children than in adults, frontal impact is more likely to occur with a fall. By contrast, frontal trauma in older individuals is partially absorbed by the frontal sinus, which diffuses the force and prevents extension of the fracture along the orbital roof. Complications of orbital roof fractures include intracranial injuries, cerebrospinal fluid rhinorrhea, pneumocephalus, pulsatile proptosis, subperiosteal hematoma, ptosis, and extraocular muscle imbalance. In roof fractures, the entrapment of extraocular muscles is rare, with most early diplopia resulting from hematoma, edema, or contusion of the orbital structures. In severely comminuted fractures, pulsating exophthalmos may occur as a delayed complication. Young children may develop nondisplaced linear roof fractures after fairly minor trauma, which may present with delayed ecchymosis of the upper eyelid. Most roof fractures do not require repair. Indications for surgery are generally neurosurgical, and treatment often involves a multidisciplinary team.

Hink EM, Wei LA, Durairaj VD. Clinical features and treatment of pediatric orbit fractures. *Ophthalmic Plast Reconstr Surg.* 2014;30(2):124–131.

Medial Orbital Fractures

Naso-orbital-ethmoidal (NOE) fractures (Fig 6-6) usually result from the face striking a solid surface and commonly involve the frontal process of the maxilla, the lacrimal bone, and the ethmoid bones along the medial wall of the orbit. Patients characteristically have a depressed bridge of the nose and traumatic telecanthus. These fractures may be categorized thus:

- Type I involve a central fragment of bone attached to canthal tendon.
- Type II are comminuted fractures of the central fragment.
- Type III involve a comminuted tendon attachment or an avulsed tendon.

Figure 6-5 Direct traumatic optic neuropathy. A middle-aged woman presents with vision loss in the right eye after sustaining head trauma from a bicycle fall. Globe examination is normal; however, a sagittal CT image demonstrates a direct traumatic optic neuropathy with an inferiorly displaced roof fracture *(arrow)* compressing the optic nerve *(arrowhead)*. *(Courtesy of M. Reza Vagefi, MD.)*

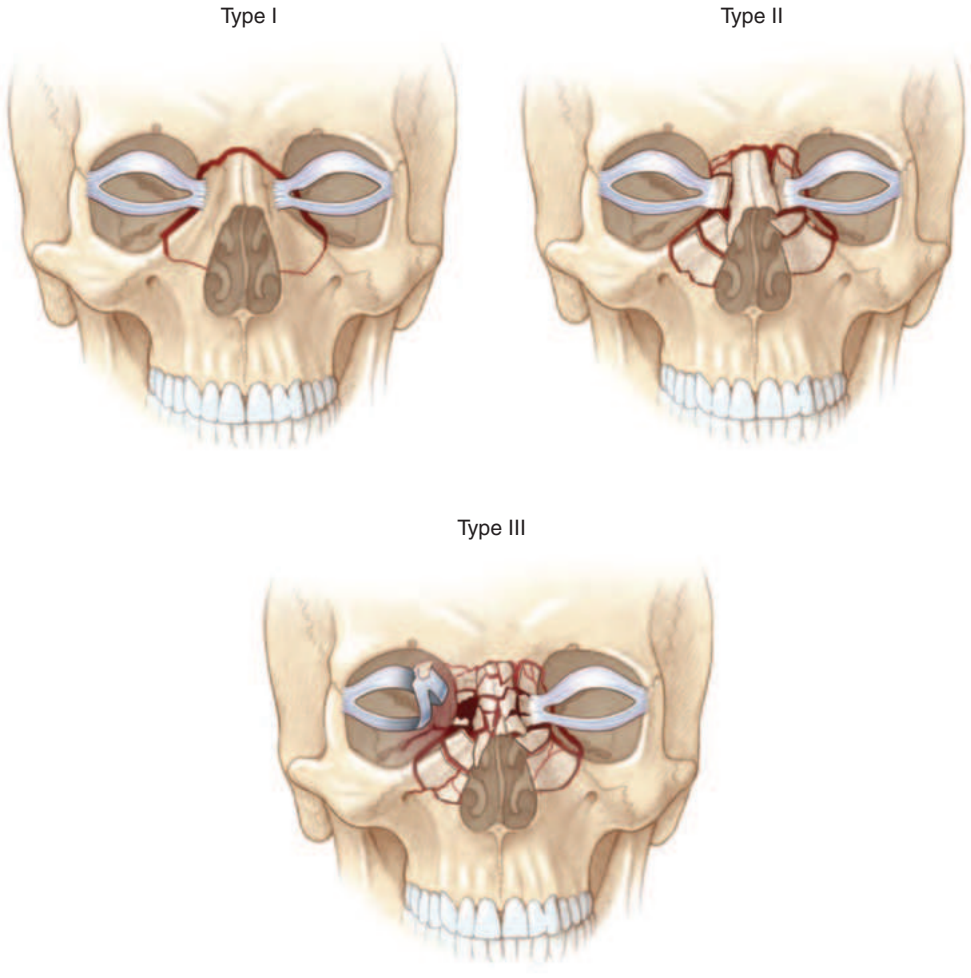

Figure 6-6 Naso-orbital-ethmoidal fractures result in traumatic telecanthus with rounding of the medial canthus. Types I–III are described according to the severity of the injury. *(Illustration by Christine Gralapp.)*

Complications associated with NOE fractures include cerebral and ocular damage, severe epistaxis due to avulsion of the anterior ethmoidal artery, orbital hematoma, cerebrospinal fluid rhinorrhea, damage to the lacrimal drainage system, lateral displacement of the medial canthus, and associated fractures of the medial orbital wall and floor. Treatment is dependent on the type of fracture; it generally includes fracture reduction and microplate fixation. Transnasal wiring of the medial canthus is used less frequently, because microplates often allow precise bony reduction.

Indirect (blow-out) fractures of the medial wall are frequently extensions of blowout fractures of the orbital floor. Isolated blowout fractures of the medial orbital wall may also occur. Surgical intervention is indicated in cases involving muscle and associated tissue entrapment, persistent restrictive diplopia, and aesthetically unacceptable enophthalmos.

Some surgeons choose to intervene on the basis of fracture size and believe the risk of enophthalmos is greatest when both the floor and the medial wall are fractured. However, determining the size of the fracture from imaging studies can be difficult. If surgery is required, the medial orbital wall can be approached by continuing the exploration of the floor superiorly along the medial wall via a lower eyelid or transconjunctival approach. An alternative approach is a medial orbitotomy through a retrocaruncular approach or, less commonly, a frontoethmoidal skin incision. See Chapter 7 in this volume for discussion of orbital surgery approaches.

Vicinanzo MG, McGwin G Jr, Allamneni C, Long JA. Interreader variability of computed tomography for orbital floor fracture. *JAMA Ophthalmol.* 2015;133(12):1393–1397.

Midfacial (Le Fort) Fractures

Le Fort fractures involve the maxilla and are often complex and asymmetric (Figs 6-7, 6-8). By definition, Le Fort fractures extend posteriorly through the pterygoid plates. These fractures may be divided into 3 categories, although clinically they often do not conform precisely to these groupings:

- *Le Fort I* fractures are low transverse maxillary fractures above the teeth, with no orbital involvement.
- *Le Fort II* fractures generally have a pyramidal configuration and involve the nasal, lacrimal, and maxillary bones as well as the medial orbital floor.
- *Le Fort III* fractures cause craniofacial disjunction, in which the entire facial skeleton is completely detached from the base of the skull and is suspended only by soft tissues. The orbital floor as well as the medial and lateral orbital walls are involved.

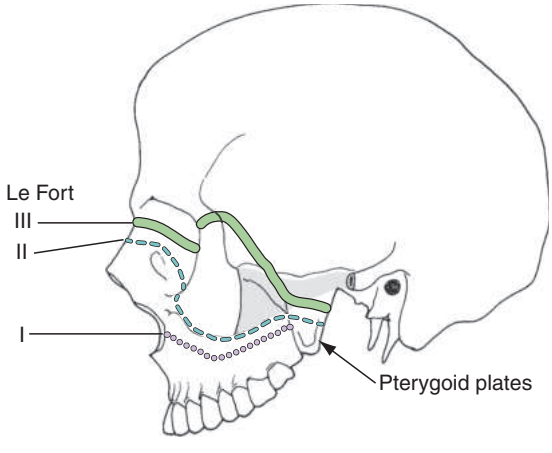

Figure 6-7 Le Fort fractures (lateral view). Note that all the fractures extend posteriorly through the pterygoid plates *(arrow). (Modified with permission from Converse JM, ed.* Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation. *2nd ed. Saunders; 1977:2.)*

Le Fort III, craniofacial disjunction. *(Modified with permission from Converse JM, ed.* Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation. *2nd ed. Saunders; 1977:2. Illustration by Cyndie C. H. Wooley.)*

Treatment may include dental stabilization with arch bars and open reduction of the fracture with rigid fixation using titanium plating systems.

Intraorbital Foreign Bodies

Orbital CT without contrast is the study of choice to localize an orbital foreign body (Fig 6-9). An organic foreign body may be difficult to visualize on CT and so is better observed on magnetic resonance imaging (MRI). However, MRI should be avoided if there is a possibility that the foreign object is ferromagnetic. Orbital ultrasonography may be helpful for foreign bodies positioned more anteriorly. Treatment of orbital foreign bodies initially involves culturing the wound (or the foreign body if it is removed) and administering antibiotics. Foreign bodies should be removed if they are composed of vegetable matter or if they are easily accessible in the anterior orbit (Fig 6-10). If an embedded foreign body causes an orbital infection that drains to the skin surface, it is sometimes possible to locate the object by surgically following the fistulous tract posteriorly. In many cases, objects can be safely observed without surgery if they are inert and have smooth edges or are located in the posterior orbit. Pellets from BB guns are common intraorbital foreign bodies and are usually best left in place.

Orbital Compartment Syndrome

Orbital compartment syndrome (OCS) is an ophthalmic emergency that occurs as a result of an acute rise in orbital pressure from hemorrhage (Fig 6-11) or introduction of air into the orbit. It most commonly occurs in association with trauma,

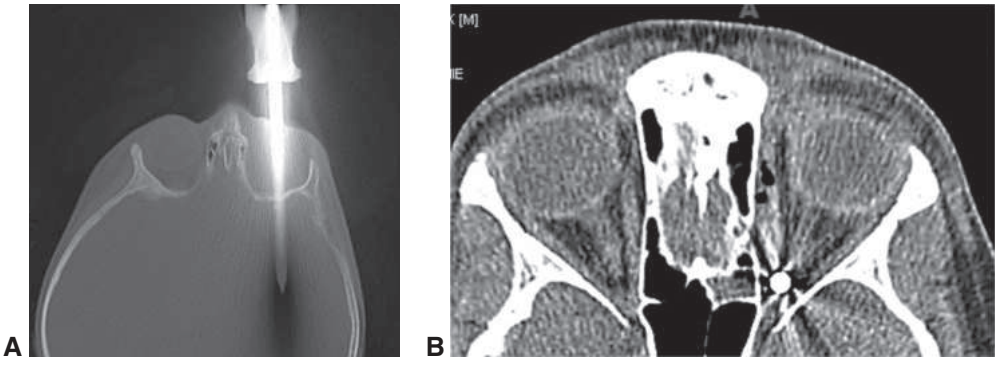

Figure 6-9 Intraorbital foreign body. **A,** Coronal CT image demonstrates a screwdriver entering the superior orbit and passing into the anterior cranial fossa. Removal required multidisciplinary approach with neurosurgery. **B,** Coronal CT image shows metallic, apical foreign body of the left orbit consistent with a BB from a BB gun. These foreign bodies can be observed without consequence as surgery to retrieve them can be dangerous. *(Courtesy of Steven M. Couch, MD.)*

FEATURES OF ORBITAL COMPARTMENT SYNDROME

Tight orbit with proptosis
Decreased visual acuity
Afferent pupillary defect
Limited motility
Elevated intraocular pressure

surgery, retrobulbar or peribulbar injections, or preexisting orbital disease (ie, venous malformations).

Because the orbit has a fixed volume, determined by rigid bony walls and dense septal attachments, there is limited room to accommodate any expansion of its contents. As

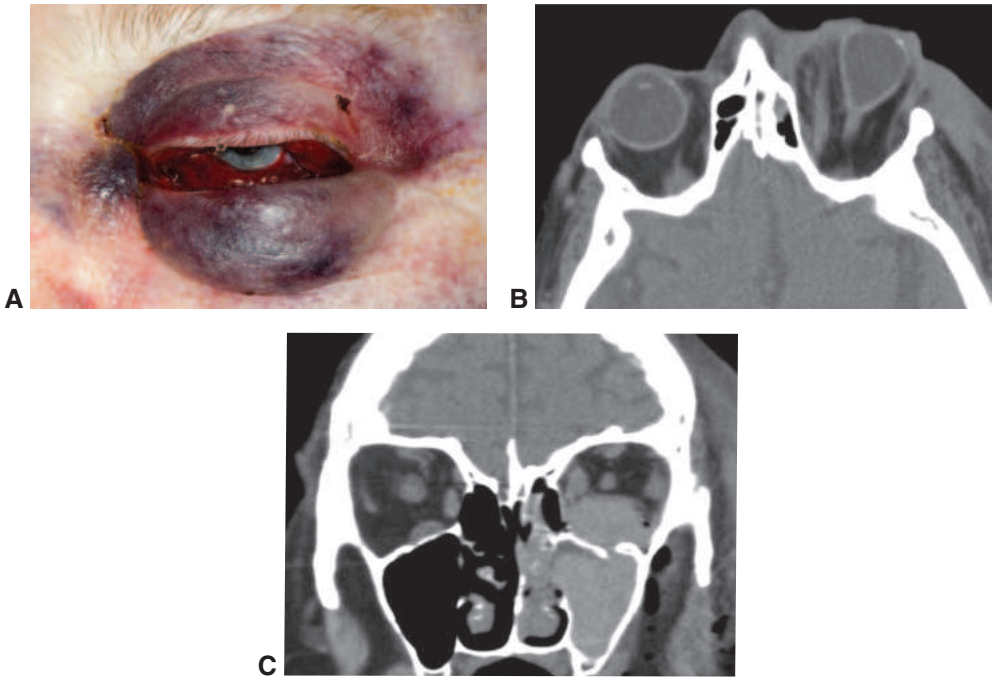

Figure 6-11 Orbital compartment syndrome (OCS). **A,** External photograph shows tense proptosis and bullous hemorrhagic chemosis. **B,** Coronal CT image shows globe tenting suggestive of stretch optic neuropathy. **C,** Axial CT image shows left orbital floor fracture with extensive intraorbital and maxillary sinus hemorrhage. *(Courtesy of Steven M. Couch, MD.)*

orbital pressure increases, associated vision loss can be attributed to 1 of the 4 following mechanisms:

- central retinal artery occlusion
- direct compressive optic neuropathy
- compression of optic nerve vasculature
- ischemic optic neuropathy that results from stretching of the optic nerve

Patients should undergo emergency decompression of the orbit, as described in the algorithm in Figure 6-12. Because vision loss can progress rapidly, this procedure should not be delayed for orbital imaging. If OCS is present in a patient with antecedent eyelid or orbital surgery, the wound should be opened and the hematoma evacuated, followed by exploration and cautery of active bleeding. Otherwise, decompression is most easily achieved by lateral canthotomy and cantholysis, in which the eyelids are disinserted from the lateral orbital rim, allowing the orbital volume to expand anteriorly. Lateral canthotomy alone does not sufficiently decrease orbital pressure; inferior cantholysis and sometimes superior cantholysis are also required. Careful monitoring and reassessment of the ophthalmic examination are necessary to determine whether further surgical intervention is needed.

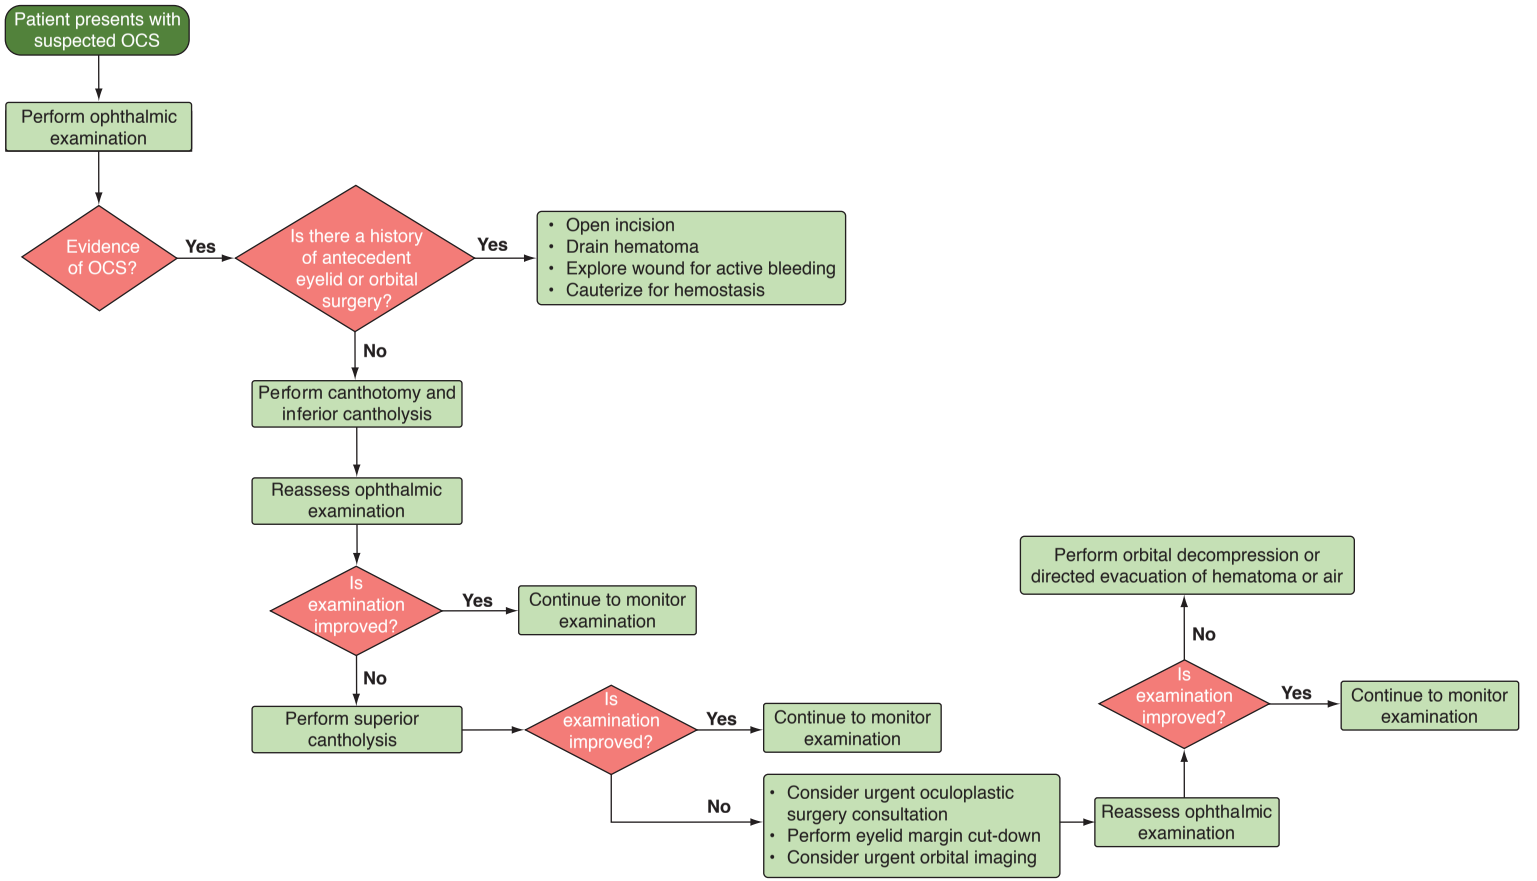

Figure 6-12 Orbital compartment syndrome treatment algorithm. The OCS treatment algorithm should be invoked for patients with decreased vision, afferent pupillary defect, and increased intraocular pressure in association with trauma, surgery, retrobulbar or peribulbar injections, or preexisting orbital disease. *(Courtesy of M. Reza Vagefi, MD.)*

Traumatic Vision Loss With Clear Media

Many patients report decreased vision following periocular trauma. It is imperative that a complete ophthalmic examination be performed to rule out direct globe injury or OCS. Reduction in visual acuity may be due to associated injuries of the cornea, lens, vitreous, retina, optic nerve, or orbit. In addition, eyelid edema may impede opening of the eyes to sufficiently clear the visual axis. However, a small percentage of patients have true vision loss without any evidence of globe injury. Vision loss in these cases suggests traumatic dysfunction of the optic nerve, also known as *traumatic optic neuropathy.* Such vision loss results from 1 of the 2 following mechanisms:

- direct injury to the optic nerve from a penetrating wound, bone fragment, or nerve avulsion
- indirect injury caused by force from a frontal blow transmitted to the intracanalicular portion of the optic nerve

The presence of an afferent pupillary defect in patients with an intact globe strongly suggests traumatic optic neuropathy. However, detection of an afferent defect may be difficult if the patient has received narcotics that cause pupillary constriction or if the traumatic optic nerve injury is bilateral and symmetric.

The details of the injury and orbital imaging can help differentiate direct optic nerve injury from indirect optic nerve injury. A penetrating injury likely indicates direct injury. History of blunt trauma to the frontal region or rapid deceleration of the cranium, often in patients who have experienced loss of consciousness, is suggestive of indirect injury. CT imaging of the orbits can demonstrate disruption of the optic nerve or fracture involving the orbital apex and/or optic canal in cases of direct injury but is often unremarkable in patients with indirect injury (see Fig 6-9).

The proper management of neurogenic vision loss after blunt head trauma is controversial. Observation alone, high-dose corticosteroids, and surgical decompression of the optic canal have been considered as treatment options for indirect traumatic optic neuropathy. However, recent studies have shown that high-dose corticosteroid therapy may not provide any additional visual benefit over observation alone, and such treatment is contraindicated in patients with concomitant traumatic brain injury. In addition, other studies have shown that decompression of the optic nerve provides no additional benefit over observation alone, while it subjects patients to the risks associated with surgery. The optimal management of indirect traumatic optic neuropathy remains unresolved. Current research is focused on neuroprotection.

Ultimately, vision loss after trauma can have serious consequences relating to employment, education, driving, and/or other daily activities. Referral for a comprehensive vision rehabilitation assessment and intervention should be an integral part of the treatment plan for the patient. Significant psychosocial issues may also need to be addressed.

Mass Casualty Incidents

A mass casualty incident (MCI) is defined as an event in which the need for emergency care exceeds the available medical resources, including personnel and equipment. With the rise of global and domestic terrorism, MCIs have unfortunately become more commonplace. Unless physicians have had prior experience treating battlefield injuries, they have undergone little training in the management of wounds arising from an MCI. An understanding of the mechanisms of injury, appropriate triage, and primary goals of initial surgery is needed to properly treat an MCI. These incidents often involve high-velocity weapons (eg, improvised explosive devices and firearms) that cause a pattern of injury different from the wounds resulting from low-velocity weapons that a trauma center would typically see. In addition, hospitals are seldom prepared for the large number of injured patients seeking treatment after an MCI occurs.

Lessons learned from physicians who have worked in combat zones have greatly improved the understanding of these types of injuries and enabled the application of these management principles in the civilian sector. On the battlefield, medics triage injured soldiers into 4 categories of urgency. The injured are stabilized accordingly and prepared for urgent medical evacuation to a combat-support hospital, where a team of specialists evaluate and surgically stabilize them. Once patients are hemodynamically stable, ophthalmic evaluation and primary surgical repair can be performed within hours of the injury. In the combat operations Enduring Freedom (2001–2014) and Iraqi Freedom (2003–2011), ocular injuries were the fourth most common injury observed. Of the soldiers sustaining ocular trauma, 85% had other systemic injuries.

In the management of an MCI, similar principles of triage and identification of immediate life-threatening injuries, with a focus on airways, breathing, and circulation, are required. Following the 2013 Boston Marathon bombing, 62% of the injured persons were transported to level I trauma centers, and 13.4% of those patients required ophthalmology consultation. These combat-medic principles allow physicians to provide the greatest benefit to the highest number of patients in the midst of chaos.

CHAPTER 7

Orbital Surgery

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- The orbit is divided into 5 surgical spaces: subperiosteal, extraconal, sub-Tenon, subarachnoid, and intraconal.
- The type of surgical approach to the orbit is based on the location of the pathology and surgical goal (biopsy, resection, fracture repair, or decompression). A sound understanding of orbital anatomy enables an appropriate surgical plan that minimizes morbidity.
- Orbital decompression surgery is performed in cases of thyroid eye disease to address compressive optic neuropathy, disfiguring proptosis, or corneal exposure.

Surgical Spaces

There are 5 surgical spaces within the orbit (Fig 7-1):

- the *subperiosteal surgical space,* which is the potential space between the bone and the periorbita (periosteum of the orbit)
- the *extraconal surgical space*, which lies between the periorbita and the muscle cone
- the *sub-Tenon surgical space,* which lies between the Tenon capsule and the globe
- the *subarachnoid surgical space,* which lies between the optic nerve and the nerve sheath
- the *intraconal surgical space*, which lies within the muscle cone

The orbit can be further divided into anterior, middle, and posterior regions, and/or superior, inferior, medial, and lateral spaces, with pathology involving one or more orbital areas. Incision planning and approach may vary based on the depth of the pathology requiring surgery.

A single orbital lesion may involve more than 1 surgical space, and a combination of approaches may be necessary to address pathologic processes affecting the orbit. An operating microscope is sometimes used, particularly for dissection inside the muscle cone. The approaches to these spaces—superior, inferior, medial, and lateral—are discussed in the following sections. Common incisions used to access these surgical spaces are shown in Figure 7-2.

Orbitotomy

Superior Approach

More orbital lesions are found in the superoanterior part of the orbit than in any other location. Lesions in this area can usually be accessed through a transcutaneous incision (Fig 7-3). When this approach is used, care must be taken to avoid damaging the levator muscle, superior oblique muscle, trochlea, and lacrimal gland.

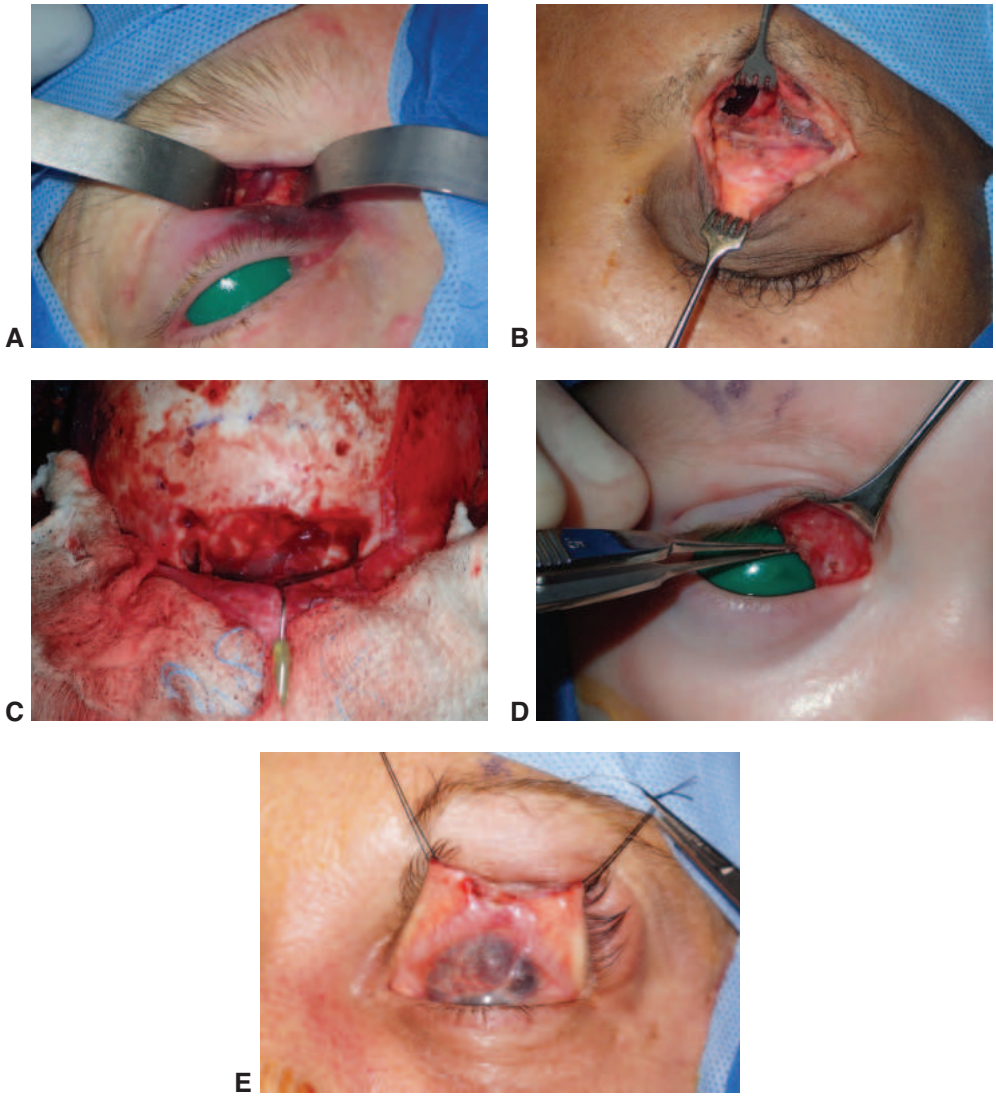

Figure 7-3 Superior orbitotomy. **A,** Medial upper eyelid approach for isolation of the superior ophthalmic vein. **B,** Sub-brow incision for superior orbit and frontal sinus mucocele. **C,** Coronal incision for sino-orbital inverting papilloma resection. **D,** Medial superior fornix incision for rhabdomyosarcoma. **E,** Vertical eyelid split incision for exposure and repair of superior scleral dehiscence from necrotizing scleritis. *(Courtesy of Steven M. Couch, MD.)*

Transcutaneous incisions

A well-hidden incision in the upper eyelid crease provides access to the superior orbital space (Fig 7-3A) and offers better cosmesis than an incision placed directly over the superior orbital rim (Fig 7-3B). Both the subperiosteal potential space and the extraconal space may be approached through this incision. To reach the subperiosteal space, dissection

is performed superiorly toward the orbital rim in a plane between the orbicularis oculi muscle and the orbital septum. An incision is then made at the arcus marginalis, where the periosteum of the frontal bone reflects to become the orbital septum, thus entering the subperiosteal space. To access the superior extraconal space, the orbital septum is divided after dissection through the skin and orbicularis muscle.

The upper eyelid crease incision may also be used for entry into the medial intraconal space. After opening the orbital septum, the surgeon identifies the medial edge of the levator muscle. Dissection is kept medial to the levator and proceeds between the medial and central fat pads, through the intermuscular septum that extends from the superior rectus muscle to the medial rectus muscle. This approach may be used for biopsy of the optic nerve, for optic nerve sheath fenestration in cases of idiopathic intracranial hypertension, or for accessing intraconal lesions medial or superior to the optic nerve.

The coronal approach to the superior orbit is most often used for skull-base tumor resections, trauma, or craniofacial surgery (Fig 7-3C). This approach is commonly employed in a multidisciplinary approach for transcranial orbitotomies to provide better access to orbital apex tumors, orbital tumors with intracranial extension, and skull-base tumors with orbital involvement.

Transconjunctival incisions

Incisions in the superior conjunctiva can be used to reach the superomedial, sub-Tenon, intraconal, or extraconal surgical spaces (Fig 7-3D). Dissection must be performed medial to the levator muscle to prevent postoperative blepharoptosis. Care should also be taken in the superolateral fornix to avoid damage to the lacrimal ductules.

Vertical eyelid splitting

Vertical splitting of the upper eyelid via a full-thickness incision allows an extended transconjunctival exposure for the removal of superomedial intraconal tumors (Fig 7-3E). Careful realignment of the tarsal plate and levator aponeurosis, similar to traumatic laceration repair, prevents postoperative blepharoptosis, eyelid notching, and eyelid retraction.

Inferior Approach

The inferior approach is useful for accessing masses that are visible or palpable in the inferior conjunctival fornix of the lower eyelid as well as for deeper inferior extraconal or intraconal orbital masses. This approach is also commonly used to approach the orbital floor for fracture repair or decompression surgery.

Transcutaneous incisions

Visible scarring can be minimized by use of a subciliary incision in the lower eyelid skin (Fig 7-4). The orbital septum is exposed through the preseptal orbicularis oculi muscle toward the inferior orbital rim. A cutaneous incision in the lower eyelid crease or directly over the inferior orbital rim can provide similar access but may leave a more noticeable scar and result in eyelid retraction. Once the skin–muscle flap is created, the surgeon can open the septum to expose the extraconal surgical space. Alternatively, for access to the

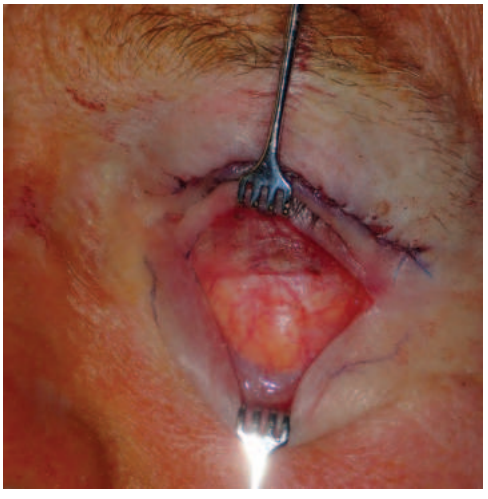

Figure 7-4 Transcutaneous lower eyelid incision for inferior approach. A well-hidden subciliary incision is made below the eyelashes, and a skin flap is elevated. An incision is then made through the orbicularis muscle to dissect in a preseptal plane to reach the inferior orbital rim. *(Courtesy of Steven M. Couch, MD.)*

inferior subperiosteal space, the periosteum is incised and elevated at the arcus marginalis to expose the orbital floor. Fractures of the orbital floor and access for orbital decompression surgery are reached by the subperiosteal route.

Transconjunctival incisions

For access to tumors and fractures of the inferior and medial orbit, the transconjunctival approach (Fig 7-5) has largely replaced the transcutaneous approach. The exposure and working space can be enlarged via a lateral canthotomy and inferior cantholysis. An incision is made through the inferior conjunctiva and lower eyelid retractors to reach the extraconal surgical space and the orbital floor. This incision is placed either in the conjunctival fornix or just below the inferior tarsal border, and the conjunctiva is placed on superior traction. When using cutting cautery, the surgeon should take care to avoid causing thermal damage to the conjunctiva and tarsus. Caution should also be taken to avoid injuring the inferior oblique muscle, inferior rectus muscle, and infraorbital neurovascular bundle. Dissection is performed in a similar fashion in a preseptal plane, inferiorly toward the orbital rim. The extraconal space can be accessed by incising the orbital septum, and the subperiosteal space can be accessed by incising at the arcus marginalis and elevating the periosteum. Further dissection between the inferior rectus and lateral rectus muscles enables access to the intraconal space.

Alternatively, an incision of the bulbar conjunctiva and Tenon capsule allows entry to the sub-Tenon surgical space. This approach is also used to gain access to the intraconal surgical space by retracting or reflecting the inferior rectus muscle from the globe.

Medial Approach

Approach to the medial orbit is used in several circumstances, including repair of medial wall trauma, orbital decompression, optic nerve sheath fenestrations, and access to

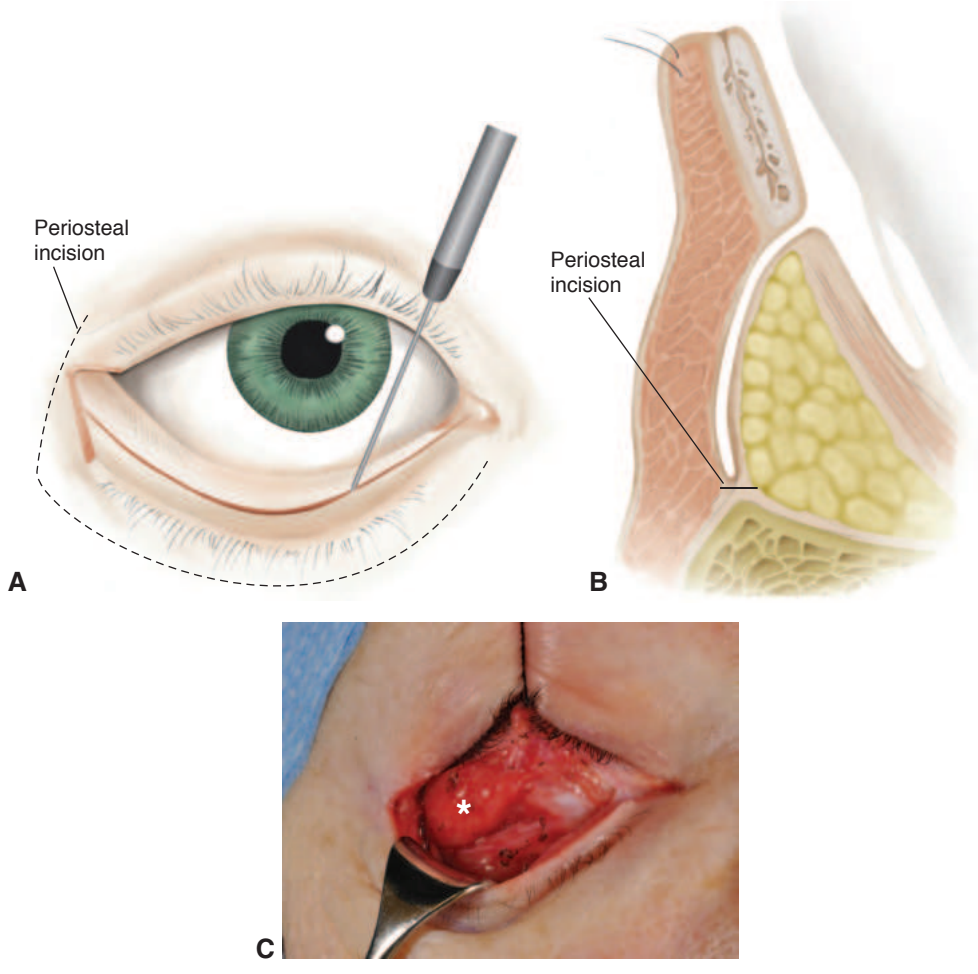

Figure 7-5 Transconjunctival approach to the inferior orbit. **A,** Conjunctival incision with or without canthotomy/cantholysis. **B,** Plane of dissection anterior to the orbital septum. **C,** The conjunctiva is placed on superior traction, and the orbital septum is opened for biopsy of an inferior extraconal mass *(asterisk).* *(Illustrations for parts A and B by Cyndie C. H. Wooley; part C courtesy of M. Reza Vagefi, MD.)*

lacrimal sac or sino-nasal tumors with orbital involvement. When dissecting in the medial orbit, the surgeon should take care to avoid damaging the medial canthal tendon, lacrimal canaliculi and sac, trochlea, superior oblique tendon and muscle, inferior oblique muscle, and the supratrochlear, infratrochlear, and supraorbital sensory nerves and vessels along the medial aspect of the superior orbital rim.

Transcutaneous incision

Tumors within or near the lacrimal sac or the frontal or ethmoid sinuses can be approached through a frontoethmoidal skin incision placed vertically, just medial to the insertion of the medial canthal tendon. This route is generally used to enter the subperiosteal

space by reflecting the medial canthal tendon in conjunction with the periosteum, thus preserving the lacrimal drainage apparatus. Incisions commonly used for external dacryocystorhinostomy also may be used to offer access to the lacrimal drainage apparatus and inferomedial orbit.

Transconjunctival incision

An incision in the bulbar conjunctiva allows entry into the extraconal or sub-Tenon surgical space (Fig 7-6A). If the medial rectus muscle is detached, the intraconal surgical space can be entered in the region of the anterior optic nerve for exploration or biopsy (Video 7-1). If the posterior optic nerve or muscle cone needs to be accessed, a combined lateral/medial orbitotomy can be performed. A lateral orbitotomy with removal of the lateral orbital wall allows the globe to be displaced temporally, maximizing medial exposure to the deeper orbit.

VIDEO 7-1 Medial transconjunctival approach for optic nerve sheath fenestration with disinsertion of medial rectus muscle. *Courtesy of Steven M. Couch, MD.*

Retrocaruncular incision

This incision may be used for repair of medial wall fractures, for medial orbital bone decompression, and for drainage of medial subperiosteal abscesses. An incision between the caruncle and plica semilunaris allows excellent exposure of the medial orbit (Fig 7-6B). Blunt dissection is carried out medially, with dissection aimed toward the posterior lacrimal crest, and followed by incision and elevation of the periosteum to gain access to the subperiosteal space. In addition, by combining the retrocaruncular incision with an inferior transconjunctival incision, panoramic exposure of the inferior and medial orbit is possible. The inferior oblique muscle may be divided at its origin along the inferomedial orbit rim and reattached at the end of surgery (Fig 7-7). This approach also provides better cosmesis than the traditional frontoethmoidal incision. However, to protect the

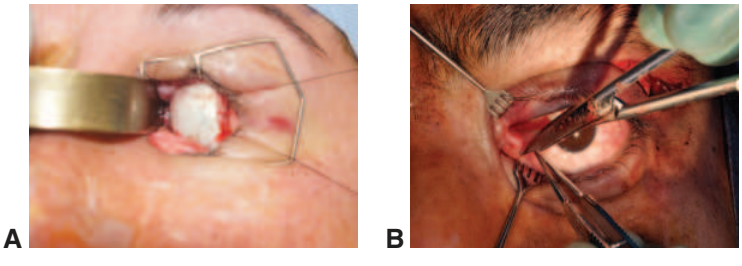

Figure 7-6 Medial orbitotomy. **A,** Medial transconjunctival orbitotomy with disinsertion of the medial rectus muscle for removal of a medial intraconal vascular tumor. Lateral bone-flap orbitotomy can be used to create additional exposure for resection, if needed. **B,** Retrocaruncular approach to the medial orbit. The retrocaruncular approach allows access to the medial orbit for procedures such as orbital decompression, repair of orbital trauma, and orbital abscess drainage. *(Part A courtesy of Steven M. Couch, MD; part B courtesy of M. Reza Vagefi, MD.)*

canaliculi, care must be taken to remain posterior to the lacrimal drainage apparatus during dissection.

Lateral Approach

A lateral approach to the orbit is used when a lesion is located within the lateral extraconal or intraconal space, behind the equator of the globe, or in the fossa of the lacrimal gland. In some cases, bone removal is required for greater access to larger pathological processes or the orbital apex. Because the orbit is relatively shallower in children than in adults, extensive exposure may be achieved in pediatric patients without the need for bone removal.

The traditional subbrow curvilinear incision (see Fig 7-2), which extends along the zygomatic arch, allows good exposure of the lateral rim but leaves a noticeable scar. It has largely been replaced by approaches through either an upper eyelid crease incision or an extended lateral canthotomy incision (Fig 7-8). With an upper eyelid crease approach, dissection is performed through the skin and orbicularis muscle, and the space between the orbicularis muscle and the septum is followed to the arcus marginalis. After an incision is made in the arcus marginalis, dissection can proceed into the subperiosteal space. Dissecting through the periorbita and then the intermuscular septum, either above or below the lateral rectus muscle and posterior to the equator of the globe, provides access to the intraconal retrobulbar space. If a lesion cannot be adequately exposed through a soft tissue lateral incision, bone removal may be required. Dissection is performed on the outside of the orbit to reflect the temporalis muscle. An oscillating saw or piezoelectric bone-cutting device is used to remove the bone of the lateral rim to provide further access (Fig 7-9). This procedure is also known as a marginotomy.

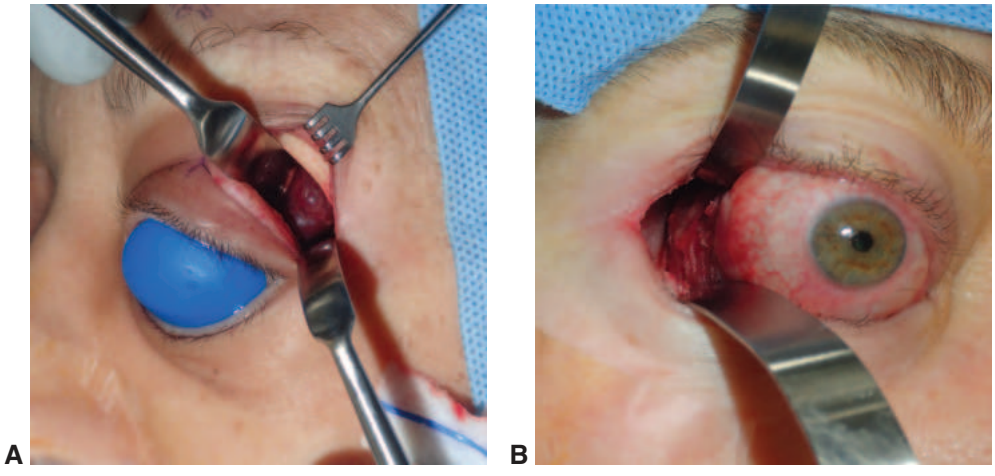

Figure 7-8 Lateral orbitotomy. **A,** Lateral upper eyelid crease incision for removal of intraconal cavernous venous malformation. **B,** Extended lateral canthotomy approach for biopsy of a lateral orbital infiltrative process. *(Courtesy of Steven M. Couch, MD.)*

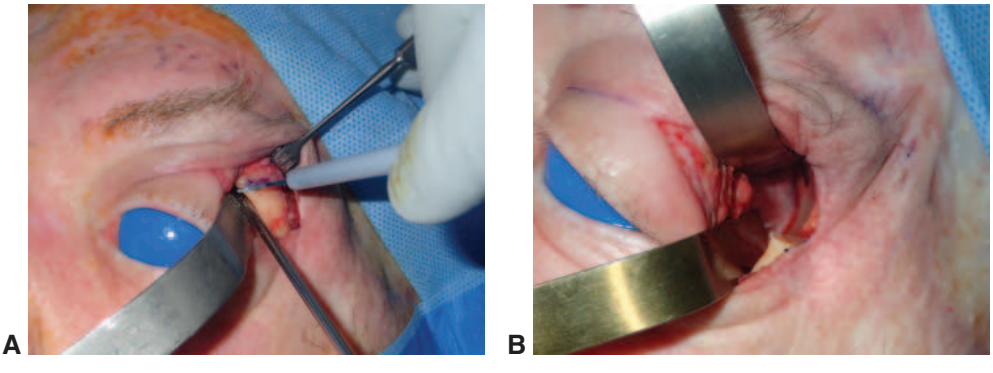

Figure 7-9 Lateral bone-flap approach to the orbital apex. **A,** Bone-flap incision is created using a piezoelectric device. **B,** After bone-flap removal, additional exposure of the orbital apex is created. *(Courtesy of Steven M. Couch, MD.)*

Complete hemostasis is achieved before closure. To help prevent postoperative intraorbital hemorrhage, an external drain may be placed in the deep orbit. The lateral orbital rim is usually repositioned and sutured back into place through predrilled tunnels. Alternatively, rigid fixation with a microplating system can be employed.

Orbital Decompression

Orbital decompression is a surgical procedure used to improve the volume-to-space discrepancy that occurs primarily in patients with thyroid eye disease (TED). The goal of orbital decompression is to allow the enlarged muscles and orbital fat to expand into the additional space that is created during the surgery (Fig 7-10). This expansion relieves

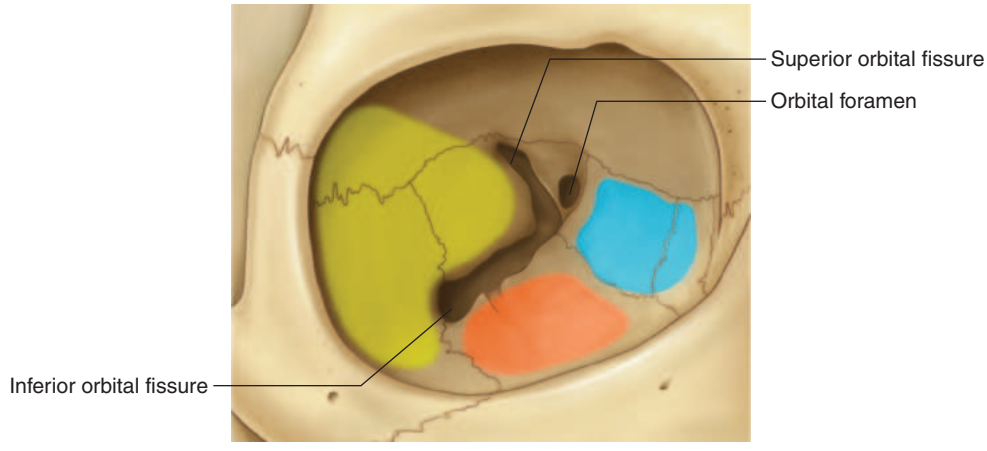

Figure 7-10 Bony anatomy of the right orbit. Potential sites for orbital decompression include the medial wall *(blue),* lateral wall *(yellow),* and floor of the orbit *(orange).* *(Courtesy of Bobby S. Korn, MD, PhD.)*

pressure on the optic nerve and its blood supply; it also reduces proptosis and orbital congestion.

Historically, decompression included removal of the medial orbital wall and much of the orbital floor, including the maxillo-ethmoidal strut, allowing the orbital tissues to expand into the ethmoid and maxillary sinuses. The approach was made through a maxillary vestibular or transcutaneous incision. However, hypoglobus and upper eyelid retraction could be exacerbated postoperatively, especially in patients with large, restricted inferior rectus muscles. This type of decompression could also disrupt globe excursion due to prolapse of the muscles into the sinus space and displacement of the orbital contents.

The approach currently used by many orbital surgeons combines 1 or more discrete incisions that allow access to the lateral, inferior, and/or medial walls. Entry to the lateral and inferior orbit is provided by an upper eyelid crease incision, an extended lateral canthotomy incision, or an inferior transconjunctival incision combined with a lateral canthotomy/inferior cantholysis. Decompression of the lateral wall can be achieved by using rongeurs, a drill, or a piezoelectric bone removal device on the greater wing of the sphenoid (Fig 7-11). A retrocaruncular incision allows an excellent approach to the medial orbital wall; it can be used in conjunction with a transconjunctival incision for further access. Alternatively, a transnasal endoscopic approach to the medial orbit via the ethmoid sinus may be used to access the medial wall.

Individualized surgical plans depend on patient variation in orbital bone size, the target for reduction in proptosis, and the surgeon's preferred method of bone removal. Some surgeons choose to decompress the orbit in a "balanced" manner by removing bone from opposing walls, believing this will reduce the risk of worsened or new-onset diplopia (Fig 7-12). Additional deep orbital fat removal can be performed in patients with significant fat hypertrophy. For further decompression, occasionally some surgeons will remove the lateral orbital rim and/or reposition it anteriorly at the time of

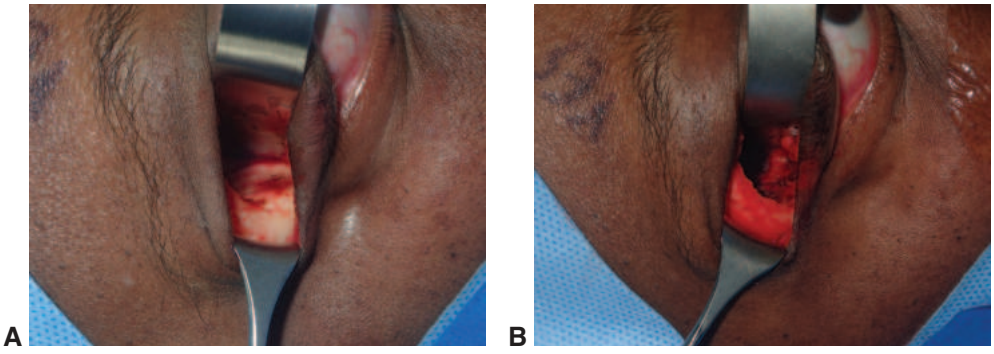

Figure 7-11 Orbital decompression surgery. **A,** Intraoperative exposure of the lateral orbital wall and greater wing of the sphenoid. **B,** Lateral wall removal with use of a piezoelectric bone aspirator. *(Courtesy of Steven M. Couch, MD.)*

Couch, MD, and Robi Maamari, MD.)*

closure. Anterior displacement of the lateral canthus may also aid in the reduction of eyelid retraction. Orbital roof decompression into the anterior cranial fossa with neurosurgical approaches is generally not performed for TED.

Traditionally, orbital decompression for compressive optic neuropathy involves expansion of the medial orbital wall and optic strut; this can be accomplished through retrocaruncular or endoscopic approaches. Some studies have shown improvement with deep lateral wall decompression and fat decompression.

Rootman DB. Orbital decompression for thyroid eye disease. *Surv Ophthalmol.* 2018;63(1):86–104.

Postoperative Care for Orbital Surgery

Measures used to reduce postoperative edema include elevation of the head, cold compresses on the eyelids, administration of systemic corticosteroids, and optional placement of a drain. Ice packs minimize swelling and allow for observation of the operative site and monitoring of visual acuity. The patient is instructed to promptly contact the surgeon to report any change of vision. Recent studies suggest that postoperative antibiotics may not be needed in most patients undergoing orbital surgery.

Fay A, Nallasamy N, Allen RC, Orbital Society, et al. Perioperative prophylactic antibiotics in 1,250 orbital surgeries. *Ophth Plast Surg.* 2020;36(4):385–389.

Special Surgical Techniques in the Orbit

Fine-needle aspiration biopsy (FNAB) may have value in selected cases, including lymphoid lesions, secondary tumors invading the orbit from the sinuses, suspected metastatic tumors, and blind eyes with optic nerve tumors (Fig 7-13). This technique is not very effective for obtaining tissue from fibrous inflammatory lesions because of the difficulty in successfully aspirating cells. Although historically FNAB has not been considered effective for biopsy in lymphoproliferative disorders, technological advances have improved its diagnostic yield when it is used in combination with flow cytometry and monoclonal antibodies or polymerase chain reaction analysis. If necessary, imaging techniques, such as ultrasonography or computed tomography, can be used to help guide the needle into the tumor. Cells (and occasionally a small block of tissue) are aspirated from the lesion. A skilled cytologist is required to study the specimen. See BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors,* for further discussion of FNAB.

Because of the anatomic relationship of the ethmoid and maxillary sinuses to the medial and inferior orbit, respectively, endoscopic transnasal surgery may be considered. Endoscopic approaches through the sinus may be considered in collaboration with head and neck surgeons. Such an approach may permit biopsy and/or resection of some orbital

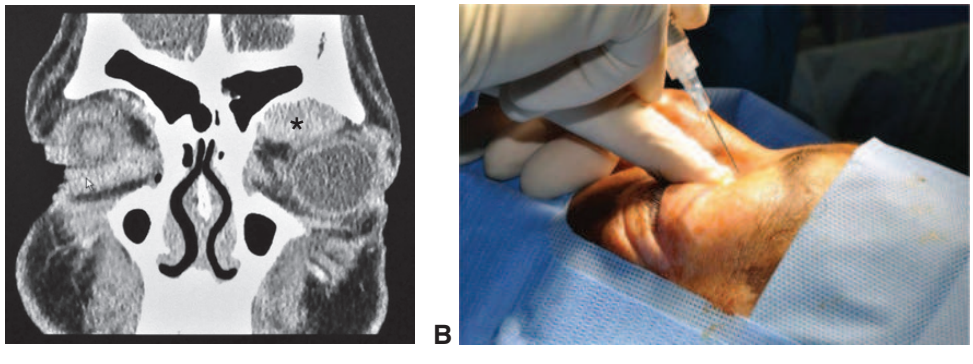

Figure 7-13 Fine-needle aspiration biopsy (FNAB). **A,** Coronal CT image of a left extraconal superomedial orbital mass *(asterisk).* **B,** FNAB is performed to avoid significant blood loss from an open biopsy and reveals metastatic hepatocellular carcinoma. *(Courtesy of M. Reza Vagefi, MD.)*

pathology. It may also be combined with open orbitotomy to allow improved access to apical processes. In addition, decompression of the orbit or optic canal may be considered for patients with TED or nontraumatic compressive optic neuropathy. Such an approach can also be used for drainage of medial subperiosteal orbital abscesses in patients with sinusitis or for debridement of necrotic tissue in patients with fungal orbital cellulitis.

Tumors and traumatic injuries of the skull base may involve the superior and posterior orbit. Advanced surgical techniques allow access to these areas via a frontal craniotomy or frontotemporal-orbitozygomatic (FTOZ) approach with a multidisciplinary team. The neurosurgeon provides the orbital surgeon with access to the deep superior and lateral orbit by removing the superior orbital rim and orbital roof. These techniques enable decompression of the optic canal as well as resection of tumors such as meningiomas, fibrous dysplasia, cavernous venous malformations, solitary fibrous tumors, schwannomas, and gliomas. Transorbital neuroendoscopic surgery (TONES) has gained popularity for utilizing standard orbital surgical approaches to provide access for neurosurgical procedures. Orbital bone removal, especially in the lateral wall and roof, allow for resection of anterior- and middle cranial fossa pathology. Rather than standard craniotomies, these less invasive approaches can lead to less morbidity and quicker recovery.

Complications of Orbital Surgery

The surgeon can reduce complications from orbital surgery by performing a complete preoperative evaluation with orbital imaging when indicated, choosing the appropriate surgical approach, obtaining adequate exposure, manipulating the tissues carefully, employing proper instrumentation and illumination, maintaining excellent hemostasis, and using a team approach when appropriate.

Decreased or lost vision is a serious complication of surgery that may be caused by excessive traction on the globe and optic nerve, contusion of the optic nerve, postoperative infection, or hemorrhage. Orbital hemorrhage may lead to increased orbital pressure and consequent ischemic injury to the optic nerve. A patient who has severe orbital pain postoperatively should be evaluated immediately for possible orbital hemorrhage. If this pain is associated with decreased vision, proptosis, ecchymosis, increased intraocular pressure, and an afferent pupillary defect, the surgeon should consider opening the wound to minimize the effects of orbital compartment syndrome (see Chapter 6 in this volume), evacuating any hematoma, controlling active bleeding, and employing hemostatic agents.

In addition to vision loss, possible complications after orbital surgery include:

- blepharoptosis
- cerebrospinal fluid leak
- ciliary ganglion dysfunction with mydriasis and loss of accommodation
- cranial neuropathy resulting in extraocular muscle weakness or palsy
- hypoesthesia in the distribution of the trigeminal nerve (divisions V_1 and V_2)
- hypoglobus of the globe after decompression

- keratitis sicca
- motility disturbance resulting in diplopia
- neurotrophic keratopathy
- orbital cellulitis
- pupillary dysfunction
- retinal detachment
- vitreous hemorrhage

CHAPTER 8

The Anophthalmic Socket

This chapter includes related videos. Go to www.aao.org/bcscvideo_section07 or scan the QR codes in the text to access this content.

Highlights

- Evisceration is removal of intraocular contents, with the sclera and extraocular muscles left intact.
- Enucleation is removal of the entire globe and a segment of the optic nerve after releasing the extraocular muscles from sclera.
- Exenteration is removal of the entire globe and either portions or all of the orbital components, including the periorbita and eyelids.
- Orbital implants may be inert or biointegrated.
- Complications of the anophthalmic socket include superior sulcus defect, conjunctival surface changes, implant exposure/infection, fornix/socket contraction, and eyelid malposition.

Introduction

Certain conditions may require removal of an eye or the orbital contents in order to safeguard life, preserve vision in the fellow eye, or enhance comfort and cosmesis.

The goals of anophthalmic socket surgery are

- assuaging clinical symptoms (ie, resolution of pain or removal of an infectious source)
- assisting in clinical diagnosis when indicated (ie, pathological diagnosis for suspected intraocular malignancies)
- maximizing orbital implant volume with good centration within the orbit
- achieving optimal eyelid contour, position, and tone
- establishing adequately deep fornices to retain the prosthesis
- transmitting motility from the implant to the overlying prosthesis
- achieving symmetry

The indications for anophthalmic surgery are diverse, and the procedure of choice varies. *Evisceration* is the removal of the cornea and intraocular contents (lens, uvea, retina, and vitreous) while leaving the sclera, extraocular muscles, and optic nerve intact. *Enucleation* involves removal of the entire globe while preserving the remaining orbital tissues.

Exenteration refers to removal of the globe and some or all of the orbital tissues (Fig 8-1). The cosmetic goals in anophthalmic surgery are to minimize any condition that draws attention to the anophthalmia. Surgical efforts to produce orbital and eyelid symmetry and to promote good prosthetic position and motility enhance cosmesis.

Congenital anophthalmia (absence of the globe), microphthalmia (diminished size of the globe), and their management are discussed in Chapter 3 of this volume. Management of infants with these disorders differs from management of adults with anophthalmia because of the opportunity for orbital and tissue expansion in infants. However, the principles of socket surgery described in this chapter may also be applied to pediatric management.

Loss of an eye may cause degraded self-image or depression. The ophthalmologist can assist patients both before and after surgery by discussing the procedure, the rehabilitation process, and expected functional changes in order to help patients with adjustment. With very few exceptions, monocular patients may resume the full range of home, vocational, and recreational activities. When resuming full activity, patients should take a cautious approach to allow adjustment to the loss of some depth perception and visual field. This loss may result in occupational limitations. Routine prosthetic maintenance and regular follow-up with an ocularist is encouraged. One of the most

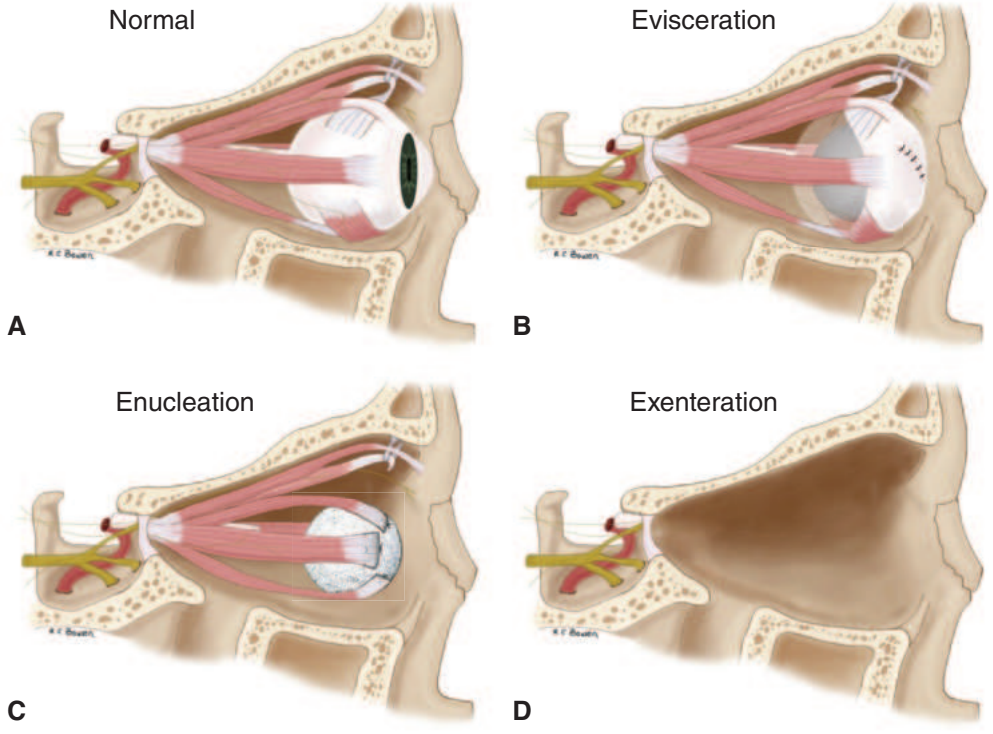

Figure 8-1 Sagittal views of anophthalmic surgical procedures. **A,** Normal. **B,** Evisceration. **C,** Enucleation. **D,** Exenteration. *(Modified with permission from Bowen RC, Ko HC, Avey GD, et al. important roles for the ophthalmologist is to help safeguard the remaining eye through regular follow-up examinations and the prescription of polycarbonate safety glasses for full-time wear.

Enucleation and Evisceration

Evisceration

Evisceration involves the removal of the contents of the globe, with the sclera, extraocular muscles, and optic nerve left intact. Evisceration should be considered *only* if the presence of an intraocular malignancy has been ruled out; if no view of the posterior chamber is possible, a B-scan ultrasound should be performed.

Advantages of evisceration

The advantages of evisceration include the following:

- *Less disruption of orbital anatomy.* Because there is less dissection within the orbit, there is a lower chance of injury to the extraocular muscles and nerves and of iatrogenic fat atrophy. The relationships between the muscles, globe, eyelids, and fornices remain undisturbed.
- *A simpler procedure.* Compared to enucleation, this procedure is faster and less invasive, and may be well suited to patients who have comorbidities, are prone to bleeding, or are overall poorer surgical candidates.
- *Easier prosthesis fitting by the ocularist.*

Disadvantages of evisceration

The disadvantages of evisceration include the following:

- *Not every patient is a candidate.* Evisceration should never be performed if a malignant ocular tumor is suspected. Severe phthisis bulbi limits the size of the orbital implant that can be placed. Patients with infectious scleritis or panophthalmitis, in which the infection has spread to involve the sclera, are not candidates unless the involved sclera can be completely removed.
- *Rare risk of sympathetic ophthalmia.*
- *Less complete specimen for pathologic examination.*

Enucleation

Enucleation involves releasing the extraocular muscles from the sclera, cutting the optic nerve, and removing the globe. Enucleation allows for complete histologic examination of the eye and optic nerve. It reduces the concern that surgery might contribute to the risk of sympathetic ophthalmia (discussed in the following paragraphs) in the fellow eye. Enucleation is the procedure of choice if the nature of the intraocular pathology is unknown or if an ocular tumor is suspected in an eye with no view of the posterior pole.

Enucleation is indicated for primary intraocular malignancies that are not amenable to alternative types of therapy. The ocular tumors that most commonly require enucleation are

retinoblastoma and choroidal melanoma. When enucleation is performed on an eye with an intraocular tumor, the surgeon must take care to avoid penetrating the globe during surgery and to handle the globe gently to minimize the remote risk of disseminating tumor cells. In cases of suspected retinoblastoma, removing a long segment of optic nerve with the enucleation specimen increases the chance of complete resection of the tumor. Blind eyes with opaque media should be suspected of harboring an occult neoplasm unless another cause of ocular disease can be surmised. Ultrasonography is useful in evaluating and planning proper management of these eyes.

In severely traumatized eyes, early enucleation may be considered if the risk of sympathetic ophthalmia and harm to the remaining eye is judged to be greater than the likelihood of recovering useful vision in the traumatized eye. Sympathetic ophthalmia is thought to be a delayed hypersensitivity immune response to uveal antigens. Enucleation with complete removal of the uveal pigment may be beneficial in preventing this subsequent immune response. The yearly incidence of sympathetic ophthalmia is estimated to be 0.03 cases per 100,000. The condition has been reported to occur from 9 days to 50 years after corneoscleral perforation. The infrequency of sympathetic ophthalmia, coupled with improved medical therapy for uveitis, has made early enucleation strictly for prophylaxis a debatable practice. (See BCSC Section 9, *Uveitis and Ocular Inflammation,* for additional information.)

Painful eyes without useful vision can be managed with enucleation or evisceration. Patients with end-stage neovascular glaucoma, chronic uveitis, or previously traumatized blind eyes can obtain dramatic relief from discomfort and improved cosmesis with either procedure. Enucleation can be performed satisfactorily under local, monitored, or general anesthesia, with 1 of the latter 2 options being typical. For debilitated patients unable to undergo surgery and rehabilitation, retrobulbar injection of ethanol or chlorpromazine may provide adequate pain relief. Serious complications associated with retrobulbar injections of ethanol include chronic orbital inflammation, fibrosis, and persistent or worsened pain.

For nonpainful, disfigured eyes without intact corneal sensation, it is generally advisable to consider a trial of a cosmetic scleral shell prior to removal of the eye. If tolerated, scleral shells can provide excellent cosmesis and motility.

Tan XL, Seen S, Dutta Majumder P, et al. Analysis of 130 cases of sympathetic ophthalmia—a retrospective multicenter case series. *Ocul Immunol Inflamm.* 2019:27(8):1259–1266.

Enucleation in childhood

Enucleation in early childhood, as well as congenital anophthalmia or microphthalmia, may lead to underdevelopment of the involved bony orbit with secondary facial and eyelid asymmetry. Orbital soft-tissue volume is a critical determinant of orbital bone growth. Thus, for an anophthalmic socket in a young child, the surgeon aims to select an implant that maximally replaces the lost orbital volume but exerts minimal tension on the wound.

In young children, autogenous dermis-fat grafts can be used successfully as primary anophthalmic implants (Fig 8-2). These grafts have been shown to grow along with the expanding orbit. The opposite effect has been observed in adults, in whom a loss of volume generally occurs when dermis-fat grafts are used as primary anophthalmic implants.

Figure 8-2 Placement of a dermis-fat graft in the left anophthalmic socket. *(Courtesy of Cat N. Burkat, MD.)*

Quaranta-Leoni FM, Sposato S, Raglione P, Mastromarino A. Dermis-fat graft in children as primary and secondary orbital implant. *Ophthalmic Plast Reconstr Surg.* 2016;32(3):214–219.

Intraoperative Complications of Enucleation and Evisceration

Removal of the wrong eye

Removal of the wrong eye is one of the most feared complications in ophthalmology. Doing an additional "time-out" immediately before enucleation or evisceration to reexamine the patient's medical record and the operative consent, and potentially to repeat ophthalmoscopy in the operating room, is of critical importance. Marking the skin near the eye to be enucleated or eviscerated after having the patient and family point to the involved eye gives further assurance.

AAO Wrong-Site Task Force, Hoskins Center for Quality Eye Care. Patient Safety Statements. *Recommendations of American Academy of Ophthalmology Wrong-Site Task Force—2014.* American Academy of Ophthalmology; 2014. https://www.aao.org/education/patient-safety-statement/recommendations-of-american-academy-ophthalmology-. Accessed November 18, 2022.

Ptosis and extraocular muscle damage

Avoiding excessive dissection, especially near the orbital roof and apex, reduces the chance of damaging the extraocular muscles, the levator muscle, and/or their innervation.

Orbital Implants

An orbital implant's function is to replace lost orbital volume, maintain the structure of the orbit, and impart motility to the overlying ocular prosthesis. Implants may be grouped according to the materials from which they are manufactured: *inert materials,* such as glass, silicone, or methylmethacrylate, and *biointegrated materials,* such as hydroxyapatite, porous polyethylene, and aluminum oxide (Fig 8-3). Biointegrated materials are designed to be incorporated by soft-tissue ingrowth from the socket.

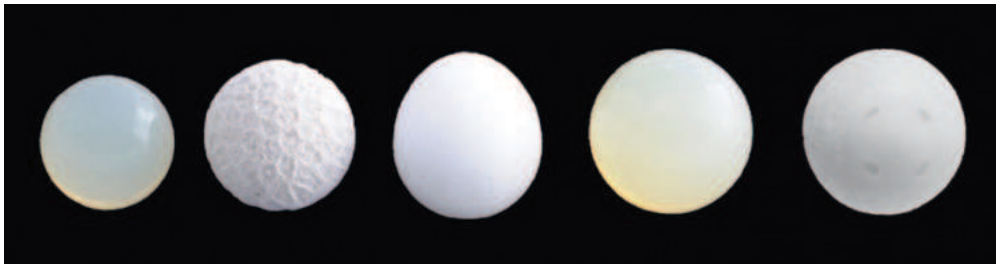

Figure 8-3 Orbital implants. Examples of various orbital implants *(from left to right)*: silicone, 18 mm; hydroxyapatite, 20 mm; porous polyethylene, 20 mm; silicone, 22 mm; porous polyethylene tunnel implant, 22 mm. *(Courtesy of Christine C. Nelson, MD.)*

Inert spherical implants provide comfort, have low extrusion rates, and are considered an appropriate and cost-effective choice in patients who don't require implant integration. Disadvantages of nonporous implants include the possibilities of decreased motility and implant migration. Spheres of inert materials may be wrapped in sclera, polyglactin mesh, or autogenous materials (eg, fascia, dermis, or muscle) to provide a substrate for attachment of the extraocular muscles as well as to serve as further barrier for migration and extrusion. Inert implants transfer motility to the prosthesis only through passive movement of the socket. Buried motility implants with anterior surface projections push the overlying prosthesis with direct force and can improve prosthetic motility.

Porous implants allow for direct attachment of the extraocular muscles as well as potential placement of a peg to incorporate the prosthesis directly with the moving implant. Peg placement is usually carried out 6–12 months after enucleation to allow for complete vascular biointegration. Although pegged porous implants offer excellent motility, they also have a higher rate of postoperative complications, including inflammation and exposure. In fact, most porous implants are never pegged and are still able to achieve adequate motility.

After enucleation, implants are placed either within the Tenon capsule or in the muscle cone behind the posterior Tenon capsule. Video 8-1 demonstrates enucleation followed by placement of an orbital implant. After evisceration, implants are placed either behind or within the sclera (see Fig 8-1). Secure closure of Tenon capsule over the anterior surface of an anophthalmic implant is an important barrier to potential later exposure.

VIDEO 8-1 Enucleation with orbital implant.
Courtesy of Catherine Y. Liu, MD, PhD.

A dermis-fat graft may be placed instead of an implant or to increase the surface area of the conjunctiva. As the conjunctiva reepithelializes over the dermis, it adds to the socket surface area.

Muscles sutured into the normal anatomical locations, either directly to the implant or to wrapping material (sclera, autogenous fascia, polyglactin mesh) surrounding the

implant, allow superior motility and prevent implant migration. Extraocular muscles may migrate and slip off the anterior surface, especially if not fixated appropriately. (Fig 8-4).

Following enucleation or evisceration surgery, an appropriately sized conformer is placed in the conjunctival fornices to maintain the conjunctival space that will eventually accommodate the prosthesis.

Wladis EJ, Aakalu VK, Sobel RK, Yen MT, Bilyk JR, Mawn LA. Orbital implants in enucleation surgery: a report by the American Academy of Ophthalmology. *Ophthalmology.* 2018;125(2): 311–317.

Prostheses

A custom ocular prosthesis is generally designed and placed after enucleation or evisceration. The ideal prosthesis is fitted to the exact dimensions of the patient's conjunctival fornices after postoperative edema has subsided (Fig 8-5). Eviscerations may be more amenable to prosthetic fitting than enucleations. Premade or stock eyes are less satisfactory cosmetically, and they also limit prosthetic motility. In addition, they may trap secretions between the prosthesis and the socket. Typically, the patient removes the prosthesis once a month for cleaning.

The American Society of Ocularists is an international nonprofit professional and educational organization that specializes in the fabrication and fitting of custom ocular prosthetics. Its website includes information for both patients and physicians (www.ocularist.org).

Figure 8-5 Right anophthalmic socket with an acceptable functional and cosmetic outcome. *(Courtesy of Keith D. Carter, MD.)*

Anophthalmic Socket Complications and Treatment

Deep Superior Sulcus

Deep superior sulcus deformity is caused by insufficient orbital volume. Initial management can begin with an ocularist adding volume to the ocular prosthesis. Nonsurgical treatment involves injection of hyaluronic acid filler or autologous fat transfer (Fig 8-6). Surgically, this deformity can be addressed through placement of a subperiosteal implant posteriorly along the orbital floor. This subperiosteal implant advances the initial implant anteriorly and superiorly to fill the superior sulcus. Alternatively, the original implant can be replaced with a larger implant or dermis-fat graft. With any fat graft, a portion of the graft is reabsorbed over the first several months.

A related problem occurs when the superior conjunctival fornix is too deep. This leads to retention and buildup of mucus and debris, causing chronic discharge and infection. This condition, which is called *giant fornix syndrome,* is treated with a superior conjunctival resection, as well as topical steroid, antibiotic, and/or povidone-iodine eyedrops when clinically indicated.

Farmer LD, Rajak SN, McNab AA, Hardy TG, Selva D. Surgical correction of giant fornix syndrome. *Ophthalmic Plast Reconstr Surg.* 2016;32(2):142–144.

Conjunctival Changes in the Anophthalmic Socket

Conjunctival cyst

Conjunctival cysts form secondary to epithelial migration beneath the surface; poor wound closure during enucleation is typically the cause. These cysts may affect prosthetic

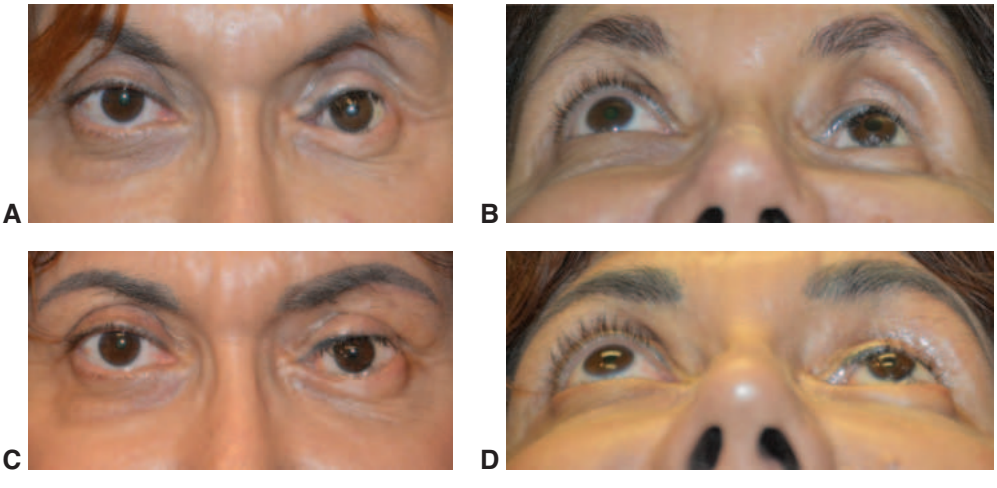

Figure 8-6 Deep superior sulcus deformity. **A, B,** Left anophthalmic socket syndrome with superior sulcus deformity and enophthalmos following multiple socket surgeries. **C, D,** Improvement in superior sulcus deformity and enophthalmos following 2 rounds of autologous fat transfer to the left orbit and periocular region. *(Courtesy of Bradford W. Lee, MD, MSc.)*

function; however, treatment is typically not necessary unless the cyst size or location interferes with comfortable prosthesis wear (Fig 8-7).

Giant papillary conjunctivitis

Giant papillary conjunctivitis (GPC) commonly develops with prosthesis wear, due to the mechanical friction between the palpebral conjunctival surface and the prosthesis. Everting the upper eyelid will demonstrate the papillae (Fig 8-8). Patients typically present with constant mucus discharge that can have a stringy consistency. Treatment consists of topical corticosteroids, topical mast cell stabilizers, and prosthetic polishing or modification, if needed.

Exposure and Extrusion of the Implant

Implants may extrude if placed too far forward, if closure of the anterior Tenon capsule is not meticulous, or if the irregular surface of the implant mechanically erodes the conjunctiva (Fig 8-9). Postoperative infection, smoking status, poor wound healing, poorly fitting prostheses or conformers, pressure points between the implant and prosthesis, and compromised vascularity may also contribute to exposure of the implant. The formation of a pyogenic granuloma, particularly if recurrent, is suggestive of implant exposure (Fig 8-10).

Exposed implants are subject to infection. Although small defects over porous implants may, in rare instances, close spontaneously, most exposures should be covered with scleral patch grafts or autogenous tissue grafts with a sufficient vascular bed to promote conjunctival healing. When implants are deeply seeded with infection, removal of the

Figure 8-10 Pyogenic granuloma of the right socket following enucleation. *(Courtesy of Bobby S. Korn, MD, PhD.)*

implant is usually required, followed by placement of an autogenous dermis-fat graft (see Fig 8-2).

Dermis-fat grafts may be used when a limited amount of conjunctiva remains in the socket. This graft increases the net amount of conjunctiva available as the conjunctiva reepithelializes over the front surface of the dermis. Dermis-fat grafts may also be used in patients with a vascularized bed of tissue or vascularized implant. Unpredictable fat resorption is a drawback to the dermis-fat graft technique in adults. However, as stated earlier, dermis-fat grafts in children appear to grow along with the surrounding orbit and may help stimulate orbital development if enucleation is required during infancy or childhood.

Contracture of Fornices

Preventing contracted fornices includes preserving as much conjunctiva as possible and limiting dissection and cautery in the fornices. Placing extraocular muscles in their normal anatomical positions along the implant also minimizes shortening of the fornices. It is recommended that the patient wear a conformer in the immediate postoperative period to maintain soft-tissue anatomy and minimize conjunctival shortening. Conformers and prostheses should not be removed for an extended period of time. The prosthesis can

be removed and cleaned, especially in the presence of infection, but should be replaced promptly after irrigation of the socket.

Contracted Sockets

Causes of contracted sockets include

- radiation treatment (usually as treatment of a tumor that necessitated removal of the eye)
- extrusion of an orbital implant
- severe initial injury (alkali burns or extensive lacerations)
- poor surgical techniques (excessive sacrifice or destruction of conjunctiva and Tenon capsule; traumatic dissection within the socket, causing excessive scar tissue formation)
- multiple ocular and/or socket operations
- removal of the conformer or prosthesis for prolonged periods

Sockets are considered contracted when the fornices are too small to retain a prosthesis (Fig 8-11). Socket reconstruction procedures involve incision or excision of the scarred tissues and placement of a graft to enlarge the fornices. Full-thickness mucous membrane grafting is preferred because it allows the grafted tissue to match conjunctiva histologically. Amniotic membrane may be used, but is often not as robust and is more prone to cicatrization, compared to mucous membrane grafts. Buccal mucosal grafts may be taken from the cheeks (the Stensen duct, which drains the parotid gland, must be avoided), the lower or upper lip, or the hard palate (the last for rigid tissue). If the graft is taken from the lip, away from the vermilion border, patients should be advised of risk of postoperative hypesthesia. Goblet cells and mucus production are preserved.

Contracture of the fornices alone (more common with the inferior fornix) is usually associated with milder degrees of socket contracture. In these cases, a buccal mucosal graft is placed in the defect, and either a symblepharon ring or a silicone bolster with sutures to the orbital rim can be used to help maintain the fornix, depending on which

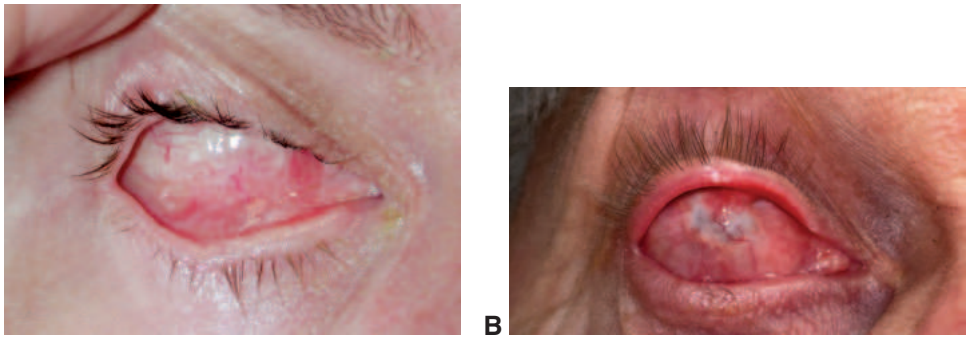

Figure 8-11 Contraction of the right anophthalmic socket with inferior forniceal shortening **(A)** and upper eyelid symblepharon to the anterior socket with forniceal shortening, which precludes prosthetic use **(B)**. *(Part A courtesy of Keith D. Carter, MD; part B courtesy of Cat N. Burkat, MD.)*

fornix is involved. The ring or bolster is left in place for at least 2 weeks, after which it can be replaced with a prosthesis or conformer.

Anophthalmic Ectropion

Lower eyelid ectropion may result from the loosening of lower eyelid support under the weight of the prosthesis. Frequent removal of the prosthesis or use of a larger, heavier prosthesis accelerates the development of eyelid laxity (Fig 8-12). Tightening the eyelid via lateral tarsal strip or canthoplasty may correct the ectropion. If needed, ectropion repair can be combined with deepening of the inferior fornix by recessing the inferior retractor muscle and grafting mucous membrane tissue.

Anophthalmic Ptosis

Ptosis in anophthalmic socket syndrome typically results from inadequate volume and, less frequently, from migration of sphere implants, cicatricial tissue in the upper fornix, or damage to the levator muscle or nerve (Fig 8-13). Small amounts of ptosis may be managed by prosthesis modification. Greater amounts require advancement of the levator aponeurosis. This procedure is best done under local anesthesia with intraoperative adjustment of eyelid height and contour because mechanical forces may cause the surgeon to underestimate true levator function. Ptosis surgery usually improves a deep sulcus by bringing the preaponeurotic fat forward. Mild ptosis may be corrected with Müller

Figure 8-14 Eyelash ptosis of the right upper eyelid and entropion of the right upper and lower eyelids following enucleation for conjunctival melanoma, which required extensive conjunctival resection and serial conjunctival map biopsies. *(Courtesy of Bradford W. Lee, MD, MSc.)*

muscle–conjunctival resection; however, this may shorten the superior fornix. Frontalis slings are often unsuccessful due to lack of visual drive to stimulate frontalis activation to elevate the eyelid.

Eyelash Margin Entropion

Eyelash margin entropion, trichiasis, and ptosis of the eyelashes (Fig 8-14) are common in patients with anophthalmic sockets. Contracture of fornices or cicatricial tissue near the eyelash margin contributes to these abnormalities. Entropion can be corrected via horizontal tarsotomy and marginal rotation surgery. Eyelash margin entropion can be corrected by splitting the eyelid margin at the gray line and grafting mucous membrane to the eyelid margin.

Cosmetic Optics

Polycarbonate spectacles with particular frame styles and tinted lenses can be used to help camouflage residual defects in the anophthalmic socket while also protecting the contralateral eye. A plus (convex) lens or minus (concave) lens may be placed in the spectacle frame in front of the prosthesis to alter the apparent size of the prosthesis. Prisms in the glasses may be used to change the apparent position of the prosthesis.

Exenteration

In exenteration, the globe and some or all of the soft tissues of the orbit are removed.

Considerations for Exenteration

Exenteration should be considered in the following circumstances:

- *Destructive tumors extending into the orbit from the sinuses, face, eyelids, conjunctiva, or intracranial space*. However, exenteration is not indicated for all such tumors, especially if clear margins cannot be obtained. In such cases, immunotherapies or radiation therapy may be alternative treatments.
- *Intraocular melanomas or retinoblastomas that have extended outside the globe (if evidence of distant metastases is excluded).* When local control of the tumor would assist in the palliative care of the patient, exenteration is indicated.

- *Malignant epithelial tumors of the lacrimal gland.* Exenteration can be considered in combination with intra-arterial carotid chemotherapy, systemic chemotherapy, and/or adjuvant radiation.
- *Fungal infection.* Subtotal or total exenteration (discussed in the next section) can be considered for the management of orbital mucormycosis. However, modern antifungal therapies are often quite effective and most studies show no significant mortality benefit associated with exenteration in this context.
- *Primary orbital malignancies that do not respond to nonsurgical therapy.*

Hirabayashi K, Idowu OO, Kalin-Hajdu E, et al. Invasive fungal sinusitis: risk factors for visual acuity outcomes and mortality. *Ophthalmic Plast Reconstr Surg*. 2019;35(6):535–542.

Types of Exenteration

Exenterations can be categorized according to the amount of tissue that is removed. Following are the types of exenteration:

- *Subtotal.* The eye and adjacent intraorbital tissues are removed so that the lesion is locally excised (leaving part of the periorbita and eyelids). This technique is used for some locally invasive tumors, for debulking of disseminated tumors, and for partial treatment in selected patients.
- *Total.* All intraorbital soft tissues, including the periorbita, are removed, with or without the skin of the eyelids (Fig 8-15A).
- *Extended.* All intraorbital soft tissues are removed, together with adjacent structures (usually bony walls and sinuses).

The technique selected depends on the pathologic process. The goal is to remove all lesions along with appropriate margins of adjacent tissue while retaining as much healthy tissue as possible. Video 8-2 demonstrates orbital exenteration. Following removal of the orbital contents, the bony socket may be allowed to spontaneously granulate and epithelialize, or it may be covered by a split-thickness skin graft (Fig 8-15B), collagen skin replacement, or regenerative tissue matrix. The graft or skin replacement may be placed

Carter, MD; part C courtesy of Cat N. Burkat, MD.)*

onto bare bone or over a temporalis muscle or temporoparietal fascial flap. Rehabilitation after exenteration may include a prosthesis attached to an eyeglasses frame, to the periorbital area (with adhesive), or to an osseointegrated implant, which may be facilitated with magnetic posts (Fig 8-16). The orbital prosthesis restores the appearance of the tissues that have been removed, including eyelids and eye, but it does not blink or move.

CHAPTER 9

Facial and Eyelid Anatomy

This chapter includes related activities. Go to www.aao.org/bcscactivity_section07 or scan the QR codes in the text to access this content.

Highlights

- A detailed understanding of eyelid and facial anatomy is critical to safe and successful surgical outcomes.
- The temporal branch of the facial nerve becomes superficial as it crosses over the zygomatic arch, and it passes inferior to the superficial temporal artery in the temporoparietal fascial plane.
- Knowledge of the vascular network of the face is important for the creation of reconstructive flaps and helps minimize the risk of intravascular injection of dermal fillers.
- Maintaining the attachment of the medial canthal tendon to the posterior lacrimal crest is critical in maintaining apposition of the eyelids to the globe.
- The inferior oblique muscle runs between the medial and central fat pads of the lower eyelid, whereas the arcuate expansion runs between the central and lateral fat pads of the lower eyelid.

Face

The structural planes of the face include skin, subcutaneous tissue, the *superficial musculoaponeurotic system (SMAS),* mimetic muscles, the deep facial fascia, retaining ligaments, and the plane containing the facial nerve, parotid duct, and buccal fat pad.

Superficial Musculoaponeurotic System and Temporoparietal Fascia

The superficial facial fascia, which is an extension of the superficial cervical fascia in the neck, invests the facial mimetic muscles to create the SMAS (Fig 9-1A, B). The SMAS distributes facial muscle contractions, facilitating facial expression. These muscle actions are transmitted to the skin by ligamentous attachments located between the SMAS and the dermis. The SMAS is also connected to the underlying bone by a network of fibrous septa and ligaments. Thus, facial support is transmitted from the deep

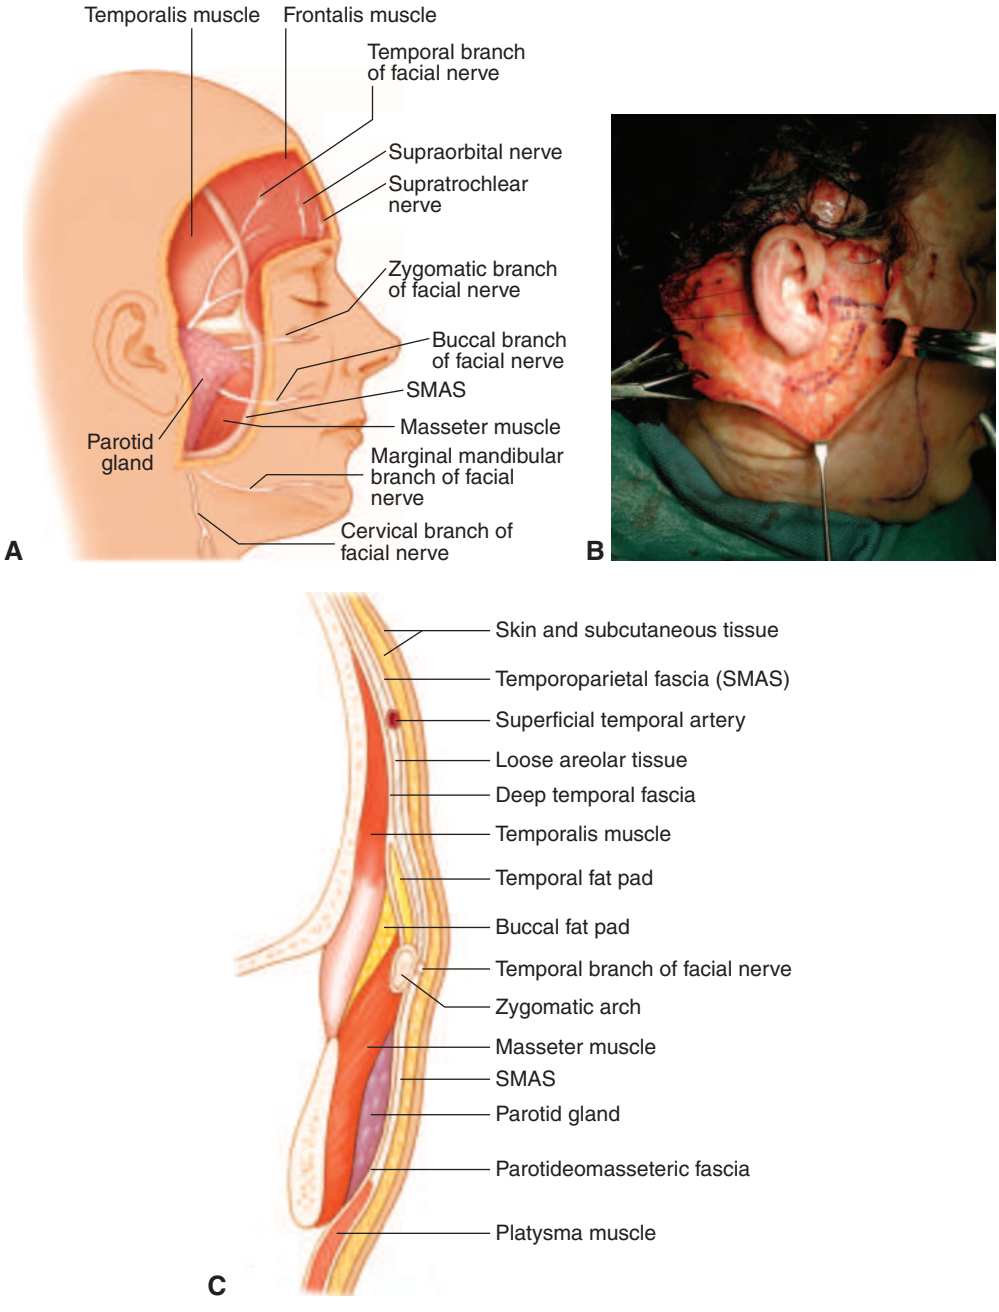

Figure 9-1 Superficial musculoaponeurotic system (SMAS). **A,** Illustration shows the SMAS; note that the facial nerve branches inferior to the zygomatic arch are deep to the SMAS. **B,** The SMAS exposed during a face-lift procedure. The horizontal surgical markings indicate the border of the zygomatic arch, and the oblique lines mark the area of planned excision of the SMAS during the procedure. **C,** Sagittal section of the face. The temporal branch of the facial nerve is found within the superficial portion of the temporoparietal fascia (an extension of the SMAS). *(Illustrations by Christine Gralapp. Clinical photo courtesy of Jill Foster, MD.)*

fixed structures of the face to the overlying dermis. There are 2 major components of this system:

- osteocutaneous ligaments (orbitomalar, zygomatic, and mandibular), which are thick fibrous attachments that originate from the bony periosteum
- fascial cutaneous ligaments (parotidocutaneous and masseteric), which are formed by a condensation of superficial and deep facial fasciae

As these ligaments become attenuated in conjunction with facial dermal elastosis, facial aging becomes apparent. Dissection and repositioning of the SMAS have important implications for facial cosmetic surgery.

As the SMAS continues superiorly over the zygomatic arch, it becomes continuous with the *temporoparietal fascia* (also called the *superficial temporal fascia*). More superiorly, the SMAS becomes continuous with the galea aponeurotica. Beneath the loose areolar tissue and the temporoparietal fascia, the deep temporal fascia of the temporal muscle splits and envelops the temporal fat pad, creating deep and superficial layers of the deep temporal fascia (Fig 9-1C).

Mimetic Muscles

The mimetic muscles (Fig 9-2) can be grouped into upper and lower face muscles.

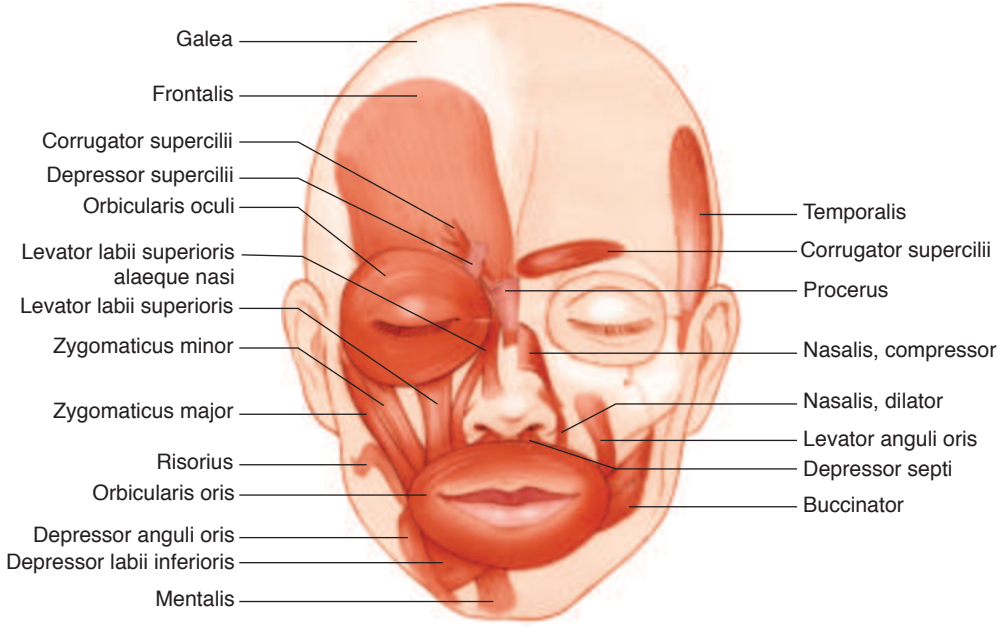

Figure 9-2 Facial mimetic muscles. *(Illustration by Christine Gralapp.)*

The upper face muscles include

- corrugator supercilii (oblique and transverse heads) (Fig 9-3), depressor supercilii, and procerus muscles that animate the glabella and medial eyebrow and cause vertical and oblique rhytids
- the orbicularis oculi muscle, which depresses the eyebrows and enables eyelid protraction (ie, closure)
- the frontalis, which is the sole elevator of the eyebrows; contraction of this muscle causes transverse forehead rhytids

The lower face muscles include

- superficial mimetic muscles, which receive their neurovascular supply on the posterior surfaces and include the platysma, zygomaticus major, zygomaticus minor, and risorius
- deep mimetic muscles, which receive their neurovascular supply anteriorly and include the buccinator, mentalis, and levator anguli oris

Other facial muscles include the orbicularis oris, levator labii superioris, levator labii superioris alaeque nasi, depressor anguli oris, depressor labii inferioris, masseter, nasalis, and temporalis.

Facial Nerve

In the neck, the superficial cervical fascia and platysma are continuous with the SMAS, and the deep cervical fascia is found on the superficial surface of the strap muscles,

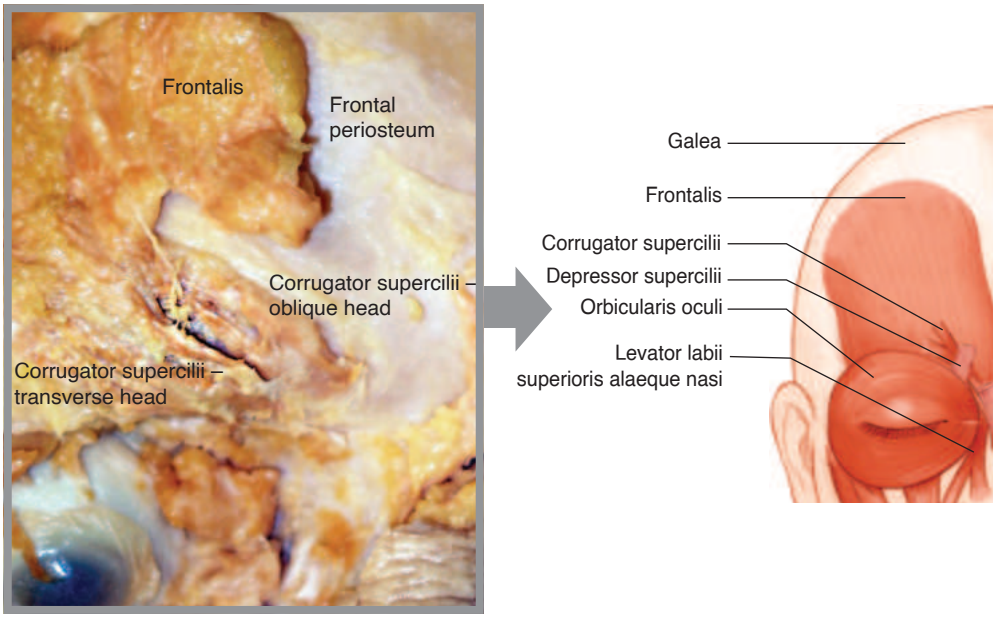

Figure 9-3 Oblique and transverse heads of the corrugator supercilii muscle. *(Photograph courtesy of Cat N. Burkat, MD; illustration by Christine Gralapp.)*

superior to the hyoid bone. The deep cervical fascia overlies the mylohyoid muscle and extends superiorly over the body of the mandible, continuing as the parotideomasseteric fascia. The facial nerve lies deep to this thin layer in the lower face. Above the zygomatic arch in the temporal region, the parotideomasseteric fascia is continuous with the deep temporal fascia, and the temporal (frontal) branch of the facial nerve lies superficial to this fascial layer. The transition of the temporal branch of the facial nerve from deep to superficial occurs as the nerve crosses over the zygomatic arch. When biopsy of the superficial temporal artery is performed, care is taken to avoid injury to the temporal branch of the facial nerve that passes just inferior to the artery, both of which lie in the temporoparietal fascial plane (Fig 9-4).

The facial nerve, cranial nerve (CN) VII, innervates the mimetic muscles and divides into 5 major branches within or deep to the parotid gland (Fig 9-5): temporal (frontal), zygomatic, buccal, marginal mandibular, and cervical. Two surgical planes help surgeons avoid CN VII when they operate: dissection on top of the deep temporal fascia (ie, temporal artery biopsy; see Fig 9-4), which is deep to the SMAS and deep to CN VII, in the upper face and temporal region; and dissection superficial to the SMAS and CN VII branches in the lower face (ie, facelift procedures).

In the temporal area, the temporal branch of CN VII (see Fig 9-5) crosses the zygomatic arch and courses superomedially in the deep layers of the temporoparietal fascia. The temporoparietal fascia is continuous with the SMAS of the lower face and the galea aponeurosis of the upper face. Deep to the temporoparietal fascia is the previously mentioned *deep temporal fascia*, a dense, immobile fascia that overlies the temporalis muscle and is continuous with the frontal periosteum (see Fig 9-1C). Dissection along this

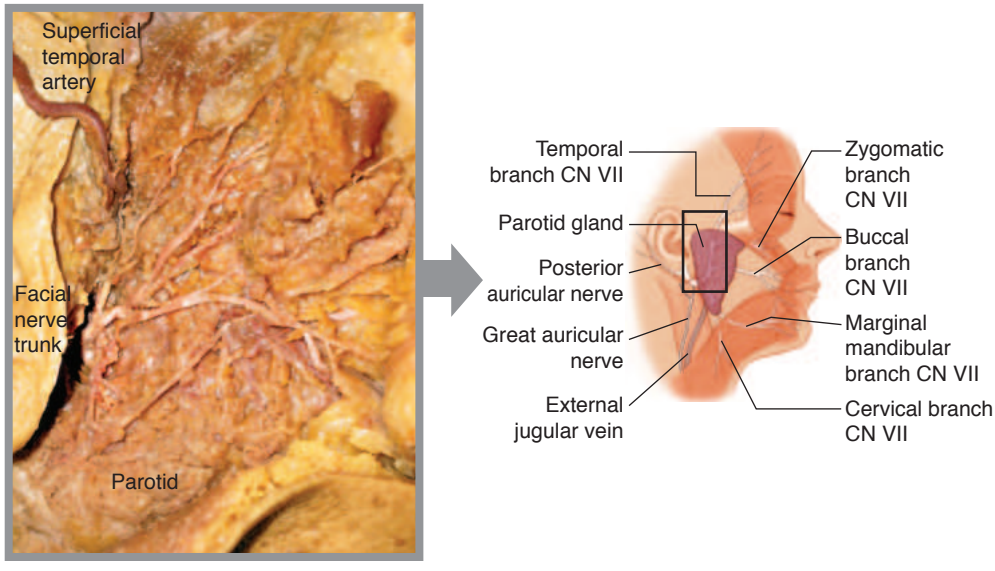

Figure 9-5 Branches of the facial nerve. *Left:* Dissection of the facial nerve showing its branching within the parenchyma of the parotid gland. *Right:* The 5 major branches of the facial nerve, cranial nerve (CN) VII. Note that the branches are buried within the parotid gland at the lateral face and become more superficial when they cross the zygomatic arch and approach the anterior edge of the SMAS. *(Photo courtesy of Cat N. Burkat, MD; illustration by Christine Gralapp.)*

fascia allows mobilization of the temporal forehead while avoiding the overlying temporal branch of the facial nerve. This anatomic principle is important when surgeons perform brow-lifting and forehead-lifting procedures. The safety zone is within 2 cm (on average) from the lateral canthus to avoid the frontal branch of the facial nerve as it crosses over the zygomatic arch (Fig 9-6).

In the lower face, the facial nerve branches, sensory nerves, vascular networks, and parotid gland and duct are deep to the SMAS (see Figs 9-1A, 9-5). Dissection just superficial to the SMAS, parotid gland, and parotideomasseteric fascia in the lower face avoids injury to these structures. The face receives sensory innervation from the 3 branches of CN V: V_1, ophthalmic; V_2, maxillary; and V_3, mandibular (Fig 9-7). Damage to these nerves causes facial numbness and paresthesia. Fortunately, overlap of the distal branches makes permanent sensation loss unusual, unless injury occurs at the proximal neurovascular bundles or with extensive distal disruption, as can be seen with a coronal incision.

Arterial Network

An understanding of the vascular supply of the eyelids and face is crucial during facial surgery, as well as when nonsurgical facial procedures, such as soft-tissue filler augmentation and neurotoxin chemodenervation, are performed. Although very rare (<0.001%–0.5% of nonsurgical facial procedures), skin necrosis can result from direct injection into a facial artery; this has been reported for every filler type. The risk is highest

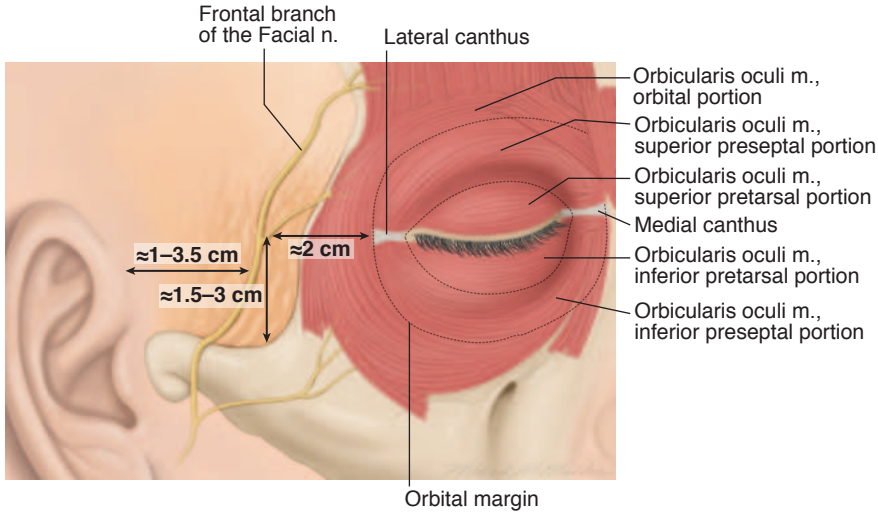

Figure 9-6 Orbicularis oculi muscle and the frontal branch of the facial nerve passing lateral to the canthal angle. *(Illustration by Mark Miller, based on a sketch by Cat N. Burkat, MD.)*

for procedures performed in the glabella, due to its limited collateral circulation; the supraorbital, supratrochlear, infraorbital, and angular arteries are the most vulnerable overall (Fig 9-8A). Early signs of arterial vascular compromise are pain and skin pallor; signs of venous occlusion often have a delayed onset, presenting as dull pain and skin discoloration.

The most devastating adverse outcome associated with soft-tissue fillers is blindness that results from occlusion of the ophthalmic artery or its branches. An intravascular bolus of filler can reach the ophthalmic artery via retrograde flow from any number of facial arteries, in particular, the dorsal nasal, angular, supratrochlear, or supraorbital vessels (Activity 9-1; Fig 9-8B, C). Vision loss is often profound (no light perception) and permanent. Dissemination of filler in a facial artery can also result in focal brain infarctions, leading to hemiplegia and dysarthria. In rare instances, vascular occlusions in the periorbital area can also result in ophthalmoplegia and ptosis.

Eyelids

The eyelids can be divided into the following 7 structural layers:

- skin and subcutaneous connective tissue
- muscles of protraction
- orbital septum
- orbital fat
- muscles of retraction
- tarsus
- palpebral conjunctiva

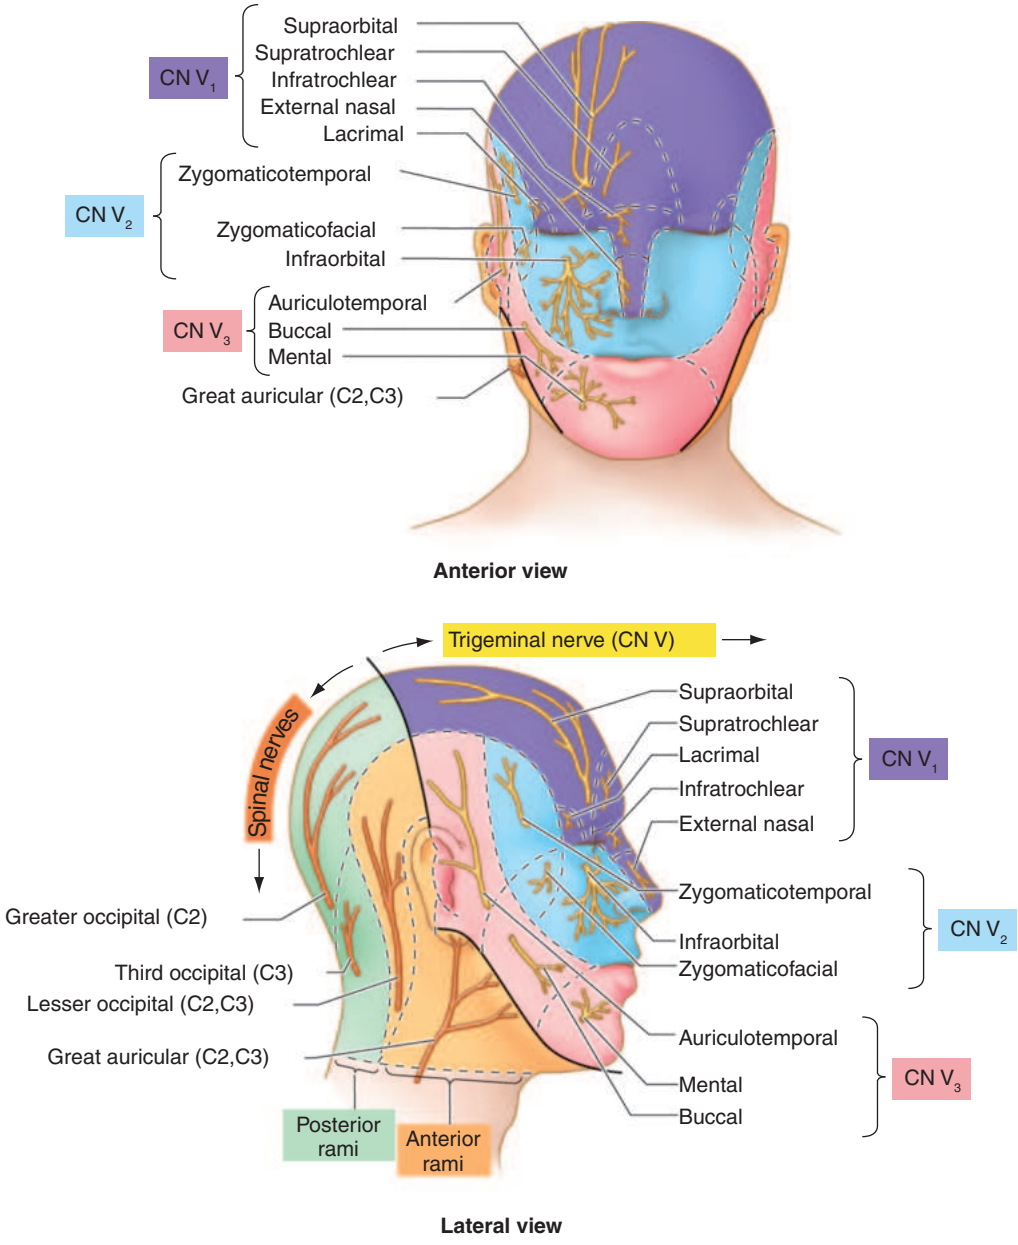

Figure 9-7 The face receives its sensory innervation from the 3 branches of CN V: V_1, ophthalmic; V_2, maxillary; and V_3, mandibular. *(Reproduced with permission from Moore KL, Dalley AF, Agur AMR.* Clinically Oriented Anatomy. *7th ed. Lippincott Williams & Wilkins; 2013:851.)*

Figure 9-9 details the anatomy of the eyelids; Activity 9-2 is an online interactive tool for self-testing knowledge of eyelid anatomy. See also BCSC Section 2, *Fundamentals and Principles of Ophthalmology,* for additional discussion and numerous illustrations.

Skin and Subcutaneous Connective Tissue

Eyelid skin is the thinnest skin of the body (~2 mm) and is unique in having no subcutaneous fat layer. Because the skin of the eyelids is subjected to constant movement (blinking), the laxity that often occurs with age is not surprising. In both the upper and the lower eyelids, the pretarsal tissues are normally firmly attached to the underlying tissues, whereas the preseptal tissues are more loosely attached, creating potential spaces for fluid accumulation. The contours of the eyelid skin are defined by the *eyelid crease* and the *eyelid fold:*

- The upper eyelid crease represents the attachments of the levator aponeurosis to the pretarsal orbicularis muscle and skin. In the eyelids of most people not of East Asian descent, this site is near or at the level of the superior tarsal border.
- The upper eyelid fold consists of the loose preseptal skin and subcutaneous tissues that rest above the confluence of the levator aponeurosis and orbital septum.

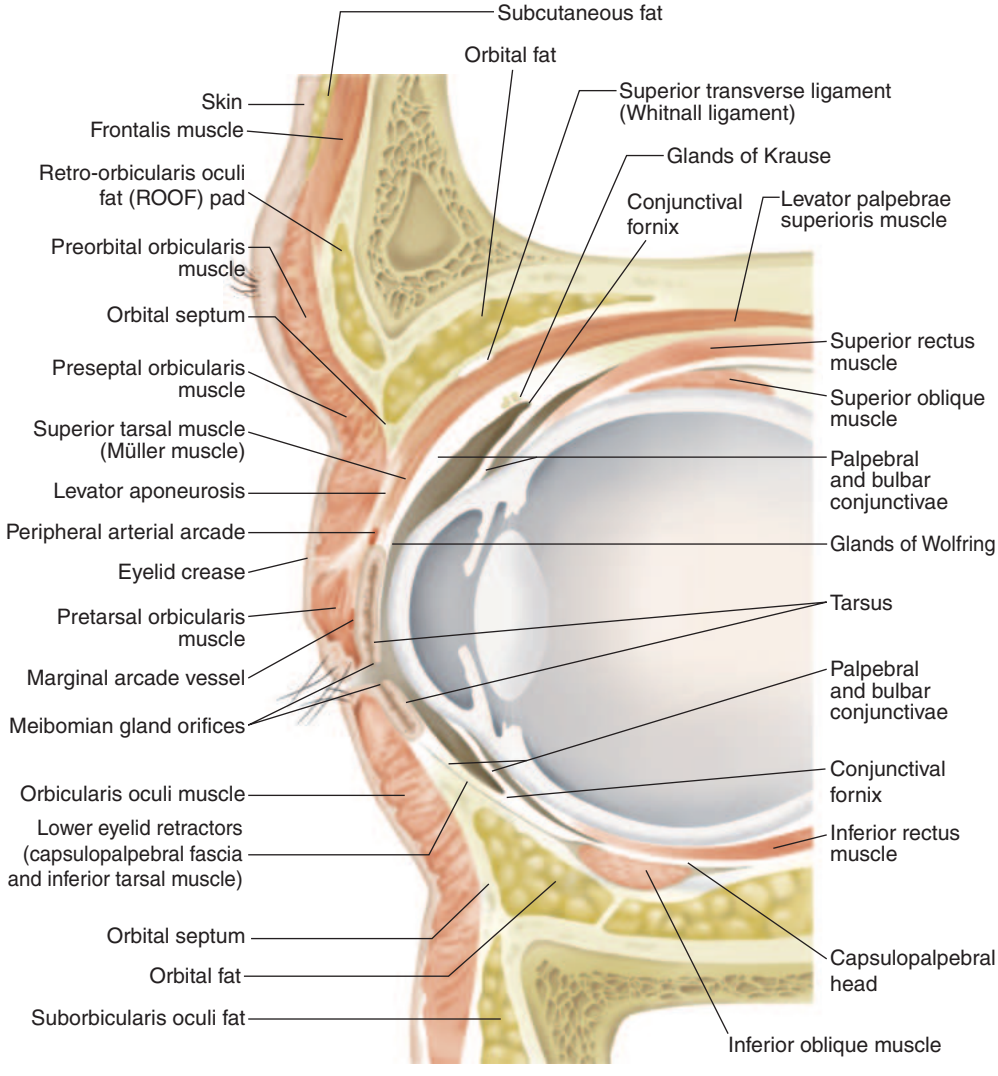

Figure 9-9 Upper and lower eyelid anatomy. *(Modified from Stewart WB.* Surgery of the Eyelid, Orbit, and Lacrimal System. *Ophthalmology Monograph 8, vol 2. American Academy of Ophthalmology; 1994:23, 85. Illustration by Cyndie C. H. Wooley.)*

ACTIVITY 9-2 Upper and lower eyelid anatomy.
Illustration modified from Stewart WB. Surgery of the Eyelid, Orbit, and Lacrimal System. *Ophthalmology Monograph 8, vol 2. American Academy of Ophthalmology; 1994:23, 85. Illustration by Cyndie C. H. Wooley.*

Racial variation can be seen in the location of the eyelid crease and eyelid fold (Fig 9-10A). The eyelid of an individual of East Asian descent usually has a relatively low upper eyelid crease because the orbital septum fuses with the levator aponeurosis between the eyelid margin and the superior border of tarsus, in contrast to an eyelid in which the fusion is supratarsal (Fig 9-10B). This also allows preaponeurotic fat to occupy a position more

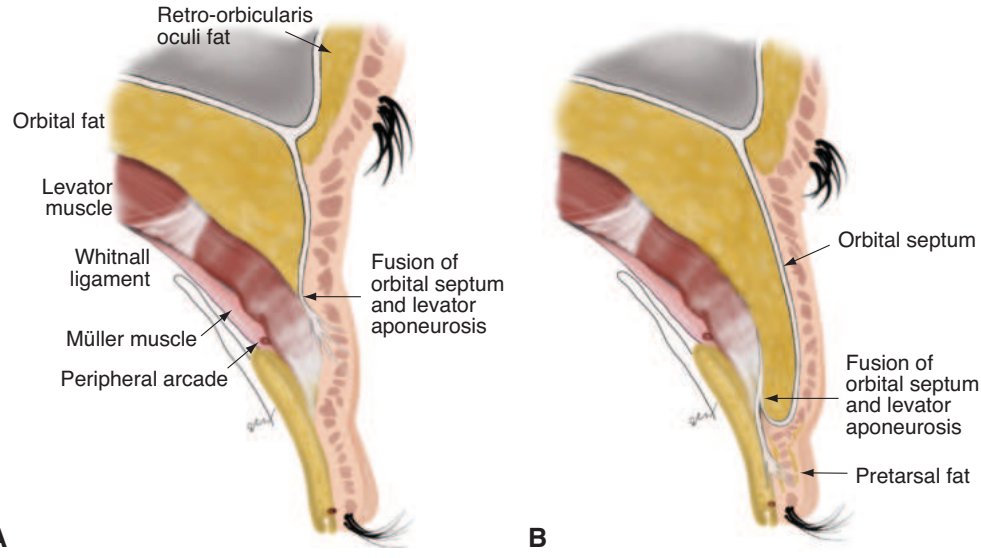

Figure 9-10 Racial variations in eyelid anatomy. **A,** Non–East Asian eyelid: the orbital septum fuses with the levator aponeurosis above the tarsus. **B,** East Asian eyelid: the orbital septum fuses with the levator aponeurosis between the eyelid margin and the superior border of the tarsus, and there are fewer aponeurotic attachments to the skin. *(Courtesy of Cat N. Burkat, MD.)*

inferior and anterior in the East Asian eyelid. Although the lower eyelid crease is less well defined than the upper eyelid crease, these differences are apparent in the lower eyelid as well.

Muscles of Protraction

The orbicularis oculi muscle is the main protractor of the eyelid. Innervated by CN VII, contraction of this muscle narrows the palpebral fissure. Specific portions of this muscle also constitute the lacrimal pump. The orbicularis oculi muscle is divided into *pretarsal, preseptal,* and *orbital* parts (Fig 9-11; see also Fig 9-6). The palpebral (pretarsal and preseptal) parts are integral to involuntary eyelid movements (blinking), whereas the orbital portion is primarily involved in forced eyelid closure.

The pretarsal orbicularis muscle arises from deep origins at the posterior lacrimal crest and superficial origins at the anterior limb of the medial canthal tendon. Near the common canaliculus, the deep heads of the pretarsal orbicularis fuse to form a prominent bundle of fibers known as the *Horner muscle,* which continues just behind the posterior limb of the medial canthal tendon to insert onto the posterior lacrimal crest. The upper and lower eyelid segments of the pretarsal orbicularis fuse in the lateral canthal area to become the lateral canthal tendon (Fig 9-12).

The preseptal orbicularis arises from the upper and lower borders of the medial canthal tendon, as a single head from the medial canthal tendon. In the upper eyelid, the preseptal muscle has an anterior head from the medial canthal tendon and a posterior head from both the superior and posterior limbs of the tendon. Laterally, the preseptal muscles form the lateral palpebral raphe.

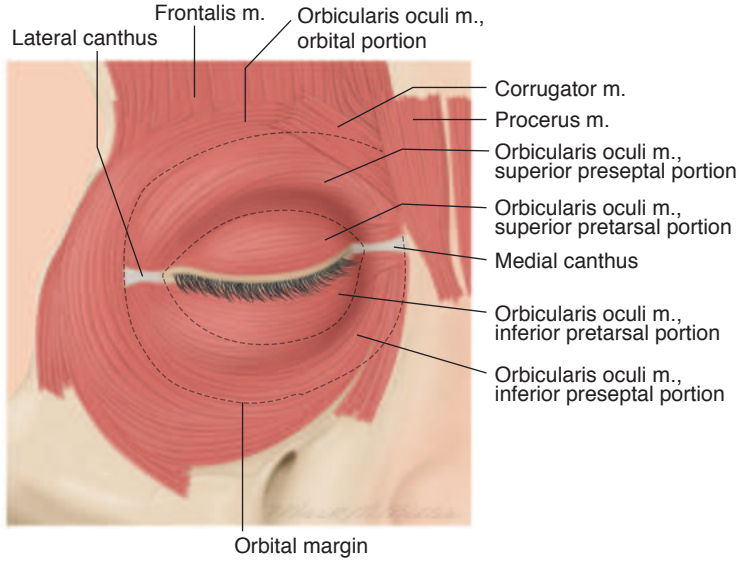

Figure 9-11 Segments of the orbicularis oculi muscle. *(Illustration by Mark Miller.)*

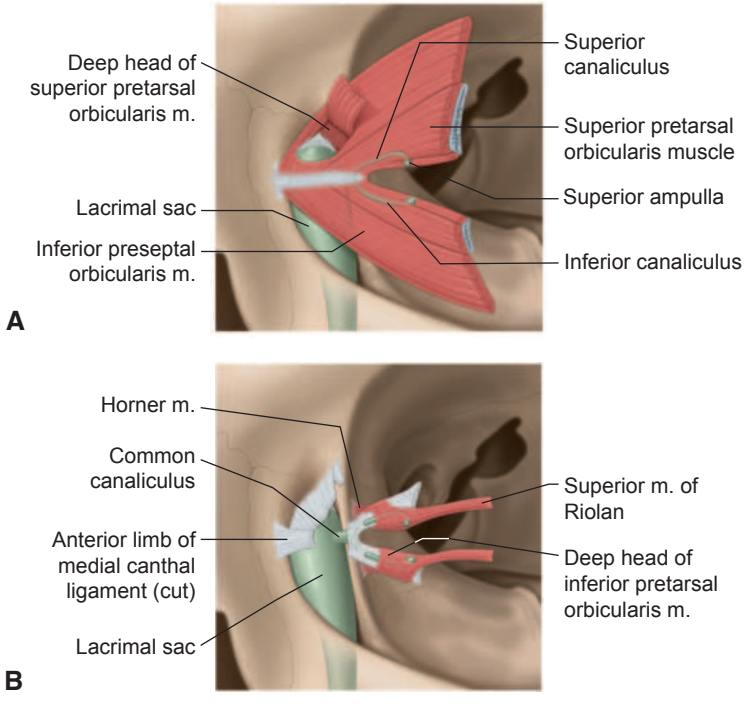

Figure 9-12 Lacrimal drainage system. **A,** Medial attachments of the orbicularis oculi muscle. **B,** Deep head of the orbicularis oculi muscle. *(Illustrations by Mark Miller.)*

The orbital portions of the orbicularis muscle arise from the anterior limb of the medial canthal tendon, the orbital process of the frontal bone, and the frontal process of the maxillary bone in front of the anterior lacrimal crest. Its fibers form a continuous ellipse and insert just below the point of origin. At the eyelid margin, a specialized bundle of striated muscle fibers, the *muscle of Riolan,* lies more posterior than the main portion of the orbicularis and creates the gray line (Fig 9-13). The muscle of Riolan may play a role in meibomian glandular discharge, blinking, and eyelash position.

Orbital Septum

The orbital septum, a thin, multilayered sheet of fibrous tissue, arises from the periosteum over the superior and inferior orbital rims at the arcus marginalis. In the upper eyelid, the orbital septum typically fuses with the levator aponeurosis 2–5 mm above the superior tarsal border, and below the superior tarsus in the eyelids of people of East Asian descent (see Figs 9-9 and 9-10). In the lower eyelid, the orbital septum fuses with the capsulopalpebral fascia at or just below the inferior tarsal border. Along with a small contribution from the inferior tarsal smooth muscle, the fused capsulopalpebral–orbital septum complex inserts on the posterior and anterior tarsal surfaces as well as the inferior border of the tarsus. Over time, thinning and attenuation of the septum and increased laxity of the orbicularis muscle contribute to anterior herniation of the orbital fat pads.

Orbital Fat

Orbital fat lies posterior to the orbital septum and anterior to the levator aponeurosis (upper eyelid) and the capsulopalpebral fascia (lower eyelid). In the upper eyelid, there are 2 fat pads: medial and central (preaponeurotic). In the lower eyelid, there are 3 fat pads: medial, central, and lateral (Fig 9-14). The inferior oblique muscle runs between the medial and central fat pads (Fig 9-15), whereas the arcuate expansion of the inferior oblique separates the central and lateral fat pads. These pockets are surrounded by thin fibrous capsules that

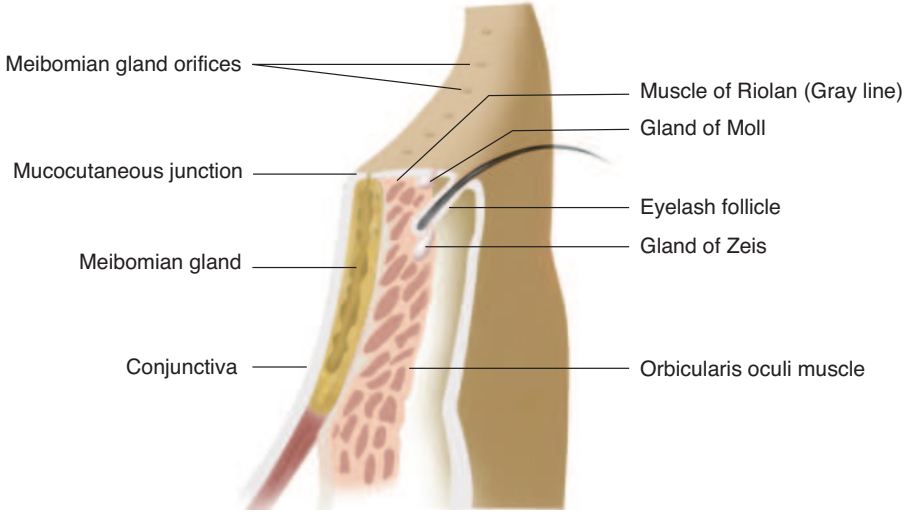

Figure 9-13 Eyelid margin anatomy. *(Illustration by Christine Gralapp.)*

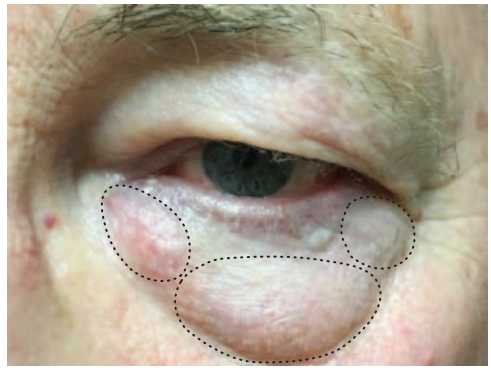

Figure 9-14 Fat pads of the left lower eyelid. *(Courtesy of Cat N. Burkat, MD.)*

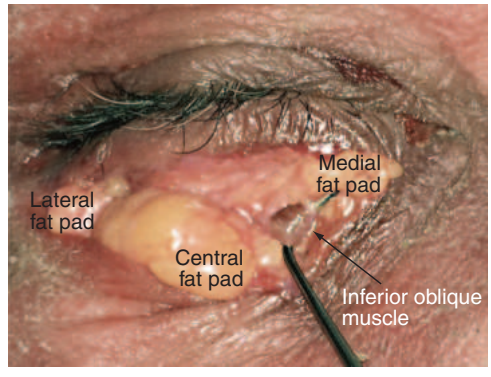

Figure 9-15 Right lower eyelid fat pads; the inferior oblique muscle is seen between the medial and central fat pads. *(Courtesy of Cat N. Burkat, MD.)*

are continuations of the anterior orbitoseptal system. The central orbital fat pad of the upper eyelid is an important landmark in both elective eyelid surgery and eyelid laceration repair because it lies directly behind the orbital septum and in front of the levator aponeurosis.

Muscles of Retraction

The upper eyelid retractors are the levator palpebrae superioris muscle with its aponeurosis and the superior tarsal muscle *(Müller muscle)*. In the lower eyelid, the retractors are the capsulopalpebral fascia and the inferior tarsal muscle.

Upper eyelid retractors

The levator muscle originates in the apex of the orbit, arising from the periorbita of the lesser wing of the sphenoid, just above the annulus of Zinn. The muscular portion of the levator is approximately 40 mm long; the aponeurosis is 14–20 mm in length (Fig 9-16). The superior transverse ligament *(Whitnall ligament)* is a sleeve of elastic fibers around the levator muscle. It is located near or above the area where the levator muscle transitions into the levator aponeurosis (Figs 9-17, 9-18).

The Whitnall ligament functions primarily as a suspensory support for the upper eyelid and the superior orbital tissues. The ligament also acts as a fulcrum for the levator, transferring its vector force from an anterior–posterior to a superior–inferior direction. Its analogue in the lower eyelid is the *Lockwood ligament*. Medially, the Whitnall ligament attaches to

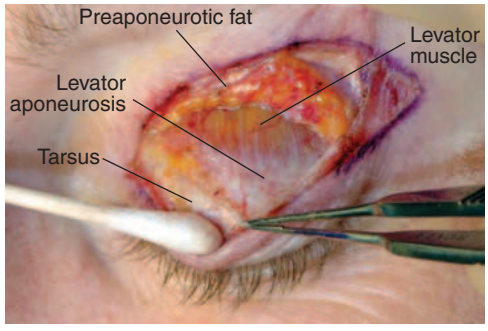

Figure 9-16 Levator muscle and aponeurosis. *(Courtesy of Cat N. Burkat, MD.)*

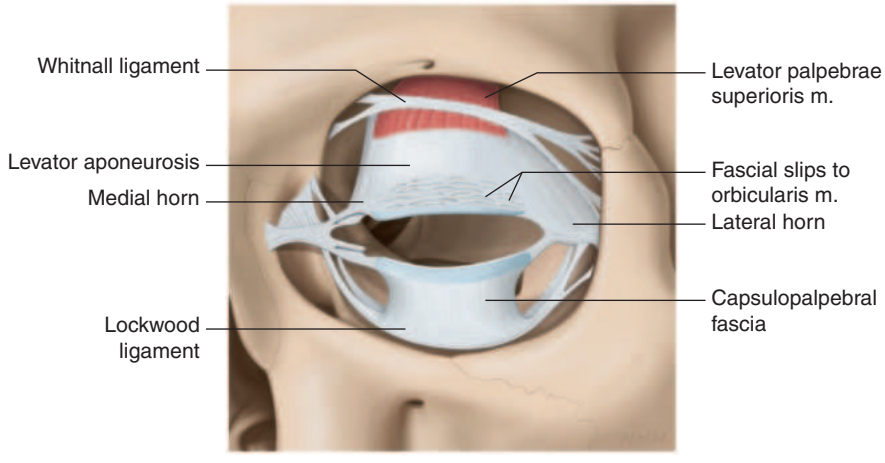

Figure 9-17 The suspensory and fibrous anatomy of the eyelid. *(Illustration by Mark Miller.)*

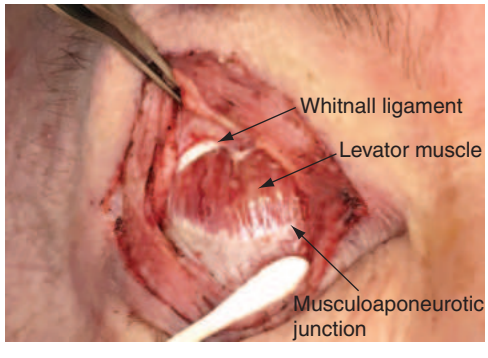

Figure 9-18 Whitnall ligament and levator complex. *(Courtesy of Cat N. Burkat, MD.)*

connective tissue around the trochlea and superior oblique tendon. Laterally, it forms septa through the lacrimal gland stroma, then arches upward to attach inside the lateral orbital wall several millimeters above the lateral orbital tubercle via attachments to the lacrimal gland fascia, with a small group of fibers extending inferiorly to insert onto the lateral retinaculum. The Whitnall ligament should not be confused with the horns of the levator aponeurosis, which lie more inferior and toward the canthi (see Fig 9-17). The lateral horn

inserts onto the lateral orbital tubercle; the medial horn inserts onto the posterior lacrimal crest. The lateral horn of the levator aponeurosis is robust and divides the lacrimal gland into the orbital and palpebral lobes; it attaches firmly to the orbital tubercle. The medial horn of the aponeurosis is more delicate and forms loose connective attachments to the posterior aspect of the medial canthal tendon and posterior lacrimal crest.

As the levator aponeurosis continues toward the tarsus, it divides into an anterior portion and a posterior portion a variable distance above the superior tarsal border. The anterior portion is composed of fine strands of aponeurosis that insert into the septa between the pretarsal orbicularis muscle bundles and skin. These fine attachments are responsible for the close apposition of the pretarsal skin and orbicularis muscle to the underlying tarsus. The upper eyelid crease is formed by the most superior of these attachments and by contraction of the underlying levator complex (see Fig 9-9). The upper eyelid fold is created by the overhanging skin, fat, and orbicularis muscle superior to the crease.

The posterior portion of the levator aponeurosis inserts firmly onto the anterior surface of the superior two-thirds of the tarsus. It is most firmly attached approximately 3 mm above the eyelid margin and is only loosely attached to the superior 2–3 mm of tarsus. Disinsertion, dehiscence, or rarefaction of the aponeurosis following ocular surgery or due to intraocular inflammation, eyelid trauma, or senescence may give rise to ptosis. The levator muscle is innervated by the superior division of CN III, which also supplies the superior rectus muscle. An isolated unilateral superior division palsy, which usually results in ptosis and decreased upgaze, implies a distal disruption of CN III.

The Müller muscle originates from the undersurface of the levator palpebrae superioris muscle approximately at the level of the Whitnall ligament, 12–14 mm above the upper tarsal border (Fig 9-19). The levator muscle divides into an anterior branch, which becomes the aponeurosis, and a posterior branch, which becomes the Müller muscle. This sympathetically innervated smooth muscle extends inferiorly to insert along the superior tarsal border. The muscle provides approximately 2–3 mm of elevation of the upper eyelid; if it is interrupted (as in Horner syndrome), mild ptosis results. The Müller muscle is firmly attached to the conjunctiva posteriorly, especially just above the superior tarsal border. The peripheral arterial arcade is found between the levator aponeurosis and the Müller muscle, just above the superior tarsal border

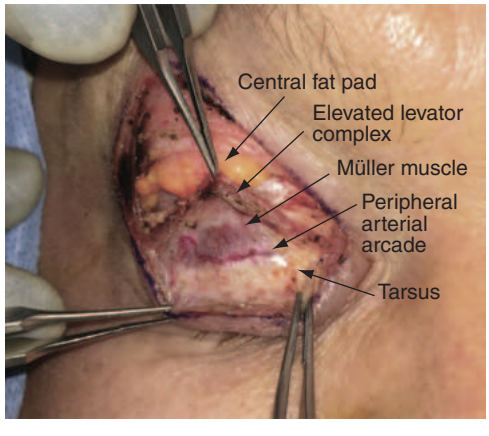

Figure 9-19 Müller muscle and peripheral arterial arcade superior to the upper tarsal border (levator complex is reflected superiorly). *(Courtesy of Cat N. Burkat, MD.)*

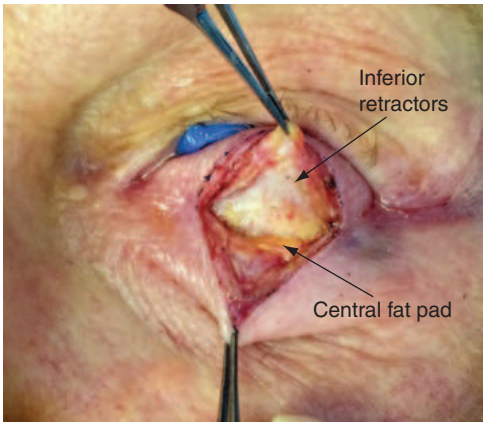

Figure 9-20 Inferior retractors of the lower eyelid include the capsulopalpebral fascia and inferior tarsal muscle. *(Courtesy of Cat N. Burkat, MD.)*

(see Fig 9-19). This vascular arcade serves as a useful surgical landmark to identify the Müller muscle.

Lower eyelid retractors

The capsulopalpebral fascia in the lower eyelid is analogous to the levator aponeurosis in the upper eyelid (Fig 9-20; see also Figs 9-9, 9-17). The fascia originates as the capsulopalpebral head from attachments to the terminal muscle fibers of the inferior rectus muscle. The capsulopalpebral head divides as it encircles the inferior oblique muscle and fuses with the sheath of the inferior oblique muscle. Anterior to the inferior oblique muscle, the 2 portions of the capsulopalpebral head join to form the Lockwood suspensory ligament. The capsulopalpebral fascia extends anteriorly from this point, sending strands to the inferior conjunctival fornix, to the inferior tarsal border after fusing with the orbital septum, and to the skin to create the eyelid crease.

The inferior tarsal muscle in the lower eyelid is analogous to the Müller muscle, although it is less well developed structurally. It runs posterior to the capsulopalpebral fascia, with smooth muscle fibers most abundant in the area of the inferior fornix.

Tarsus

The tarsi are firm, dense plates of connective tissue that serve as the structural support for the eyelids (Fig 9-21). The upper eyelid tarsal plate measures 10–12 mm vertically at the central eyelid in people not of East Asian descent but is roughly 2 mm shorter in the eyelids of individuals of East Asian descent; the lower eyelid tarsal plate measures 4 mm. The tarsal plates are typically 1 mm thick and taper at the ends to form rigid attachments to the periosteum through the medial and lateral canthal tendons. They may become horizontally displaced with age as a result of stretching of the medial and lateral supporting tendons, and matrix metalloproteinases may play a role in remodeling the tarsus contributing to floppy eyelid in patients with sleep apnea. The meibomian glands within the tarsus are modified holocrine sebaceous glands.

Conjunctiva

The palpebral conjunctiva is composed of nonkeratinized stratified squamous epithelium. It forms the posterior layer of the eyelids and contains the mucin-secreting goblet cells and

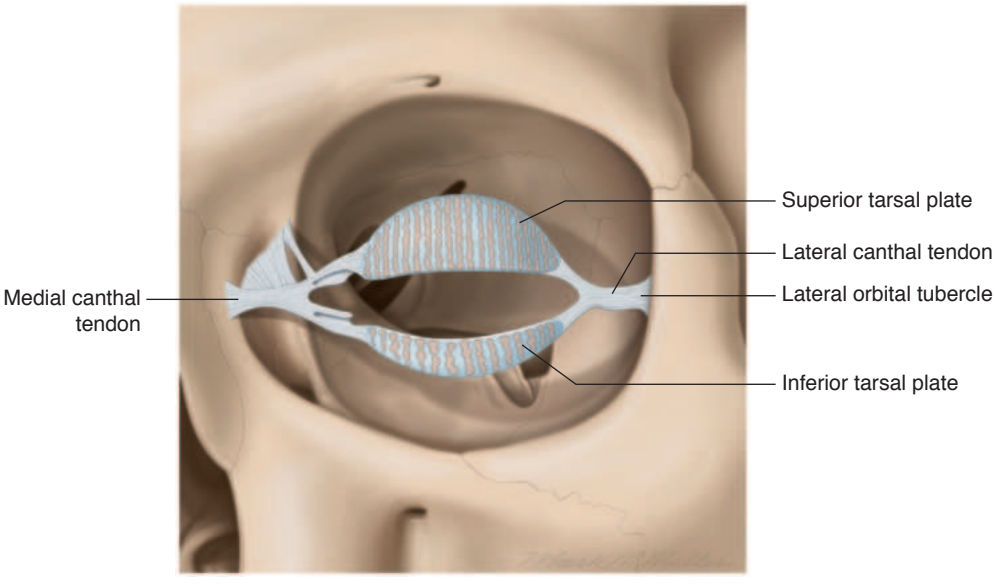

Figure 9-21 Tarsal plates and suspensory tendons of the eyelid. *(Illustration by Mark Miller.)*

the accessory lacrimal *glands of Wolfring* and *Krause* (see Fig 9-9). The accessory lacrimal glands are found in the subconjunctival tissue mainly in the upper and lower eyelids. The glands of Wolfring are found primarily along the nonmarginal tarsal borders, and the glands of Krause are found in the fornices.

Additional Anatomical Considerations

Connective tissue

Suborbicularis fat pads Deep to the orbicularis muscle, overlying the maxillary and zygomatic periosteum, is a plane of nonseptate fat called the *suborbicularis oculi fat (SOOF).* This fat is analogous to the superiorly located *retro-orbicularis oculi fat (ROOF),* which is situated deep to the eyebrow and extends into the eyelid, where it merges with postorbicularis fascia in the upper eyelid (Fig 9-22).

The medial and lateral SOOF are deep fat pads of the cheek, located below the inferior orbital rim, and play an important role in the gradual gravitational descent of the midfacial soft tissues that occurs with age. Repositioning of the SOOF can support involutional, cicatricial, and paralytic ectropion of the lower eyelid. In aesthetic procedures, elevation of the SOOF restores more youthful contours in the lower eyelid and midfacial soft tissues.

The ROOF is the brow fat pad located deep above the superior orbital rim. It also undergoes gravitational descent, compounding redundant dermatochalasis and fullness. The descended ROOF, which is whiter and more fibrous, should not be confused with prominent prolapsed yellow preaponeurotic fat in the upper eyelid. In some patients, it is necessary to reposition the descended ROOF to the frontal periosteum during blepharoplasty to achieve an adequate functional and aesthetic result. The ROOF and SOOF can also become enlarged in patients with thyroid eye disease.

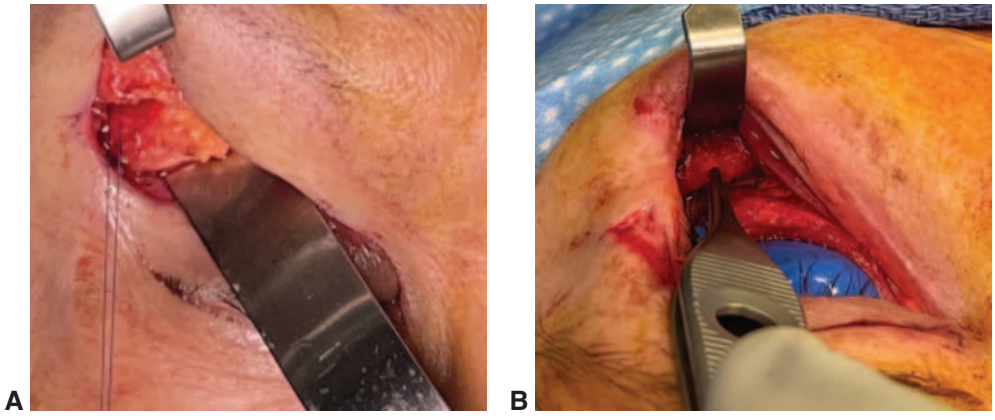

Figure 9-22 Suborbicularis fat pads. **A,** Retro-orbicularis oculi fat (ROOF) identification as part of an internal lateral browpexy procedure. **B,** Sub-orbicularis oculi fat (SOOF) lift as an adjunct to transconjunctival lower eyelid blepharoplasty. *(Courtesy of Lilangi S. Ediriwickrema, MD.)*

Canthal Tendons

The configuration of the palpebral fissure is maintained by the medial and lateral canthal tendons in conjunction with the attached tarsal plates (see Fig 9-21). The 2 origins of the medial canthal tendon from the anterior and posterior lacrimal crests fuse just temporal to the lacrimal sac; they then split again into an upper limb and a lower limb that attach to the upper superior and lower inferior tarsal plates. The attachment of the tendon to the periosteum overlying the anterior lacrimal crest is diffuse and strong. The attachment to the posterior lacrimal crest is more delicate but is important in maintaining apposition of the eyelids to the globe, which allows the puncta to lie in the tear lake.

Stretching or disinsertion of the medial canthal tendon may cause cosmetic or functional problems such as telecanthus (Fig 9-23). Trauma to the medial canthus can result in canaliculus-involving lacerations and medial canthal avulsion with poor apposition. Severe trauma can result in naso-orbital-ethmoidal (NOE) fractures with varying degrees of damage to the lacrimal and ethmoid bones as well as to the medial canthal tendon, which can lead to medial canthal dystopia, epistaxis, and lacrimal damage (see Chapter 6).

The lateral canthal tendon attaches at the lateral orbital tubercle 2–5 mm inside the lateral orbital rim. It splits into superior and inferior limbs that attach to the respective tarsal plates. Horizontal eyelid instability is frequently the result of lateral canthal tendon lengthening, which can cause tearing and ectropion (see Chapter 14, Fig 14-4, for an illustration of the lacrimal pump mechanism). The lateral canthal tendon usually inserts 2 mm higher than the medial canthal tendon, giving the horizontal palpebral fissure a natural upward slope from medial to lateral. Insertion of the lateral canthal tendon inferior to the medial canthal tendon causes the horizontal palpebral fissure to slant downward.

Eyelid margin

The eyelid margin is the confluence of the mucosal surface of the conjunctiva, the edge of the orbicularis, and the cutaneous epithelium. Along the margin are eyelashes and glands,

Figure 9-23 Traumatic telecanthus, right side. *(Courtesy of Cat N. Burkat, MD.)*

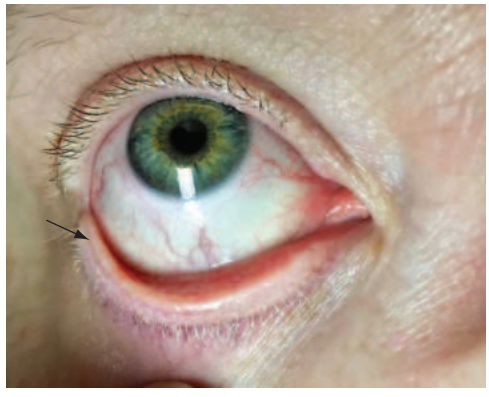

Figure 9-24 Eyelid margin gray line, which is the terminal end of the muscle of Riolan, or the pretarsal orbicularis muscle *(arrow)*. *(Courtesy of Cat N. Burkat, MD.)*

which provide protection for the ocular surface. The *gray line* is an isolated section of pretarsal orbicularis muscle (Riolan muscle) just anterior to the tarsus (Fig 9-24; also see Fig 9-13). The mucocutaneous junction is located posterior to the meibomian gland orifices on the eyelid margin. The horizontal palpebral fissure is approximately 30 mm long. The main portion of the margin, called the *ciliary margin,* has rather well-defined anterior and posterior edges. Medial to the punctum and in the lateral quarter of the eyelid the eyelid margin is thinner.

Eyelashes

There are approximately 100 eyelashes, or cilia, on the upper eyelid and 50 on the lower eyelid. The eyelashes originate in the anterior lamella of the eyelid margin, just anterior to the tarsal plate, and form 2 or 3 irregular rows. A few cilia may be found in the caruncle.

Meibomian glands

The meibomian glands are sebaceous glands that contribute to the lipid layer of the tear film via modified holocrine secretion. They originate in the tarsus and number approximately 30–40 in the upper eyelid and 20 in the lower eyelid. During the second month of gestation, both the eyelashes and meibomian glands differentiate from a common pilosebaceous unit. This dual potentiality explains why, following trauma or chronic irritation, an eyelash follicle may develop from a meibomian gland *(acquired distichiasis).* Similarly, an extra row of eyelashes arising from the meibomian orifices may be present from birth *(congenital distichiasis).*

Figure 9-25 Periocular lymphatic drainage. *(Illustration by Cyndie C. H. Wooley. Reproduced from Jordan DR, et al.* Surgical Anatomy of the Ocular Adnexa. Ophthalmology Monograph 9. *American Academy of Ophthalmology; 1996:95.)*

Vascular and lymphatic supply

The extensive vascularity of the eyelids promotes healing and helps defend against infection. The arterial supply of the eyelids comes from 2 main sources: (1) the internal carotid artery by way of the ophthalmic artery and its branches (supraorbital and lacrimal) and (2) the external carotid artery by way of the arteries of the face (angular and temporal). Collateral circulation between these 2 systems is extensive, anastomosing throughout the upper and lower eyelids and forming the marginal and peripheral arcades (see Fig 9-9).

The *marginal arterial arcade* should not be confused with the peripheral arterial arcade. In the upper eyelid, the marginal arcade lies 2 mm superior to the margin, near the follicles of the cilia and anterior to the tarsal plate. The *peripheral arcade* lies superior to the tarsus, between the levator aponeurosis and the Müller muscle (see Figs 9-9, 9-19). The lower eyelid often has only 1 arterial arcade, located at the inferior tarsal border.

Eyelid venous drainage may be divided into a *preseptal* system, in which the preseptal tissues drain into the angular vein medially and into the superficial temporal vein laterally, and a *postseptal* system, in which drainage flows into the orbital veins and the deeper branches of the anterior facial vein and pterygoid plexus (see BCSC Section 5, *Neuro-Ophthalmology*). Lymphatic vessels serving the medial portion of the eyelids typically drain into the submandibular lymph nodes. Lymphatic channels serving the lateral eyelids drain first into the superficial preauricular nodes and then into the deeper cervical nodes (Fig 9-25). This has implications for eyelid malignancies and potential metastatic spread.

CHAPTER 10

Eyelid Disorders and Neoplasms

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- Eyelids can be affected by congenital, acquired, infectious, inflammatory, and neoplastic conditions.
- Congenital ptosis seen in blepharophimosis syndrome typically requires frontalis suspension for adequate elevation.
- Epithelial hyperplasias, or papillomas, are the most common type of benign eyelid lesions.
- Targeted immune therapies for various cutaneous malignancies continue to evolve.
- Radiation therapy is not an acceptable primary treatment modality for sebaceous carcinoma.

Congenital Anomalies

Congenital anomalies of the eyelid may be isolated or associated with other eyelid, facial, or systemic anomalies. Careful evaluation of patients with hereditary syndromes is helpful before proceeding with treatment. Most congenital anomalies of the eyelids are rare and occur during the second month of gestation as a result of developmental arrest or failure of fusion. (See also BCSC Section 6, *Pediatric Ophthalmology and Strabismus.*)

Blepharophimosis–Ptosis–Epicanthus Inversus Syndrome

Blepharophimosis–ptosis–epicanthus inversus syndrome (BPES), also called *blepharophimosis syndrome,* is typically autosomal dominant in inheritance, although sporadic variants can occur. Classic findings include the following:

- blepharophimosis (profound shortening of the horizontal palpebral fissures)
- severe bilateral ptosis, often with poor levator function
- epicanthus inversus (a fold of skin extending from the lower eyelid to the medial canthus)
- telecanthus (increased soft-tissue distance between the medial canthi)

The syndrome is caused by variants in the *FOXL2* gene, located on chromosome 3. There are 2 types of BPES (types I and II), and both involve abnormalities of the eyelids. In

addition to the characteristics listed above, findings may include lateral lower eyelid ectropion secondary to vertical eyelid deficiency, flat nasal bridge, superior orbital rim hypoplasia, ear deformities, high-arched eyebrows, and hypertelorism (Fig 10-1). Type I is also associated with premature ovarian failure and infertility or reduced fertility in women.

Multiple surgical procedures may be required and are often performed in a staged fashion, but a priority should be the timely prevention of amblyopia due to visually obstructive ptosis. Medial canthal repositioning is typically addressed first with multiple Z-plasties (Fig 10-2) or with Y–V-plasties, sometimes combined with repositioning of the medial canthal tendons via transnasal wiring or suture fixation to a plate; however, horizontal traction on the upper eyelid may exacerbate the ptosis. Surgery for correction of ptosis often requires a frontalis sling due to poor levator function. Other procedures may be necessary to address ectropion or orbital rim hypoplasia.

Congenital Ptosis of the Upper Eyelid

Congenital ptosis of the upper eyelid is discussed in Chapter 12.

Congenital Ectropion

Congenital ectropion rarely occurs as an isolated finding. It is more often associated with BPES, Down syndrome, or ichthyosis, a condition characterized by dry, scaly, and thickened

Burkat, MD.)*

skin. Congenital ectropion is caused by a vertical insufficiency of the anterior lamella of the eyelid and may give rise to chronic epiphora and exposure keratitis. Mild congenital ectropion usually requires no treatment. If the condition is severe and symptomatic, surgical correction is similar to that used for cicatricial ectropion, with vertical lengthening of the anterior lamella with full-thickness skin grafting, and, frequently, horizontal tightening of the lateral canthal tendon.

Complete eversion of the upper eyelids occasionally occurs in newborns (Fig 10-3). Possible causes include anterior lamellar inflammation or shortage, inclusion conjunctivitis, and Down syndrome. Topical lubrication and short-term patching of both eyes may be curative. Full-thickness sutures or temporary tarsorrhaphy is used when necessary, followed by definitive repair.

Euryblepharon

Euryblepharon is characterized by horizontal lengthening of the lower eyelids and may be associated with BPES (Fig 10-4A). The lateral portion of the eyelid is typically more involved, having a downward slant and lateral ectropion due to an inferiorly displaced lateral canthal tendon. Impaired blinking and lagophthalmos may lead to exposure keratitis. If the condition causes symptoms, reconstruction may include lateral canthal repositioning along with suspension of the suborbicularis oculi fat to the lateral orbital rim to support the lower eyelid. If excess horizontal length is present, a lateral tarsal strip or eyelid margin resection may be required. Occasionally, skin grafts may be necessary.

Ankyloblepharon

Ankyloblepharon is a partial *(ankyloblepharon filiforme adnatum)* or complete fusion of the eyelid margins (Fig 10-4B). These webs of skin can usually be opened with scissors after being clamped for a few seconds with a hemostat. In severe cases, underlying ocular abnormalities may exist.

Figure 10-3 Congenital eyelid eversion. *(Courtesy of Thaddeus S. Nowinski, MD.)*

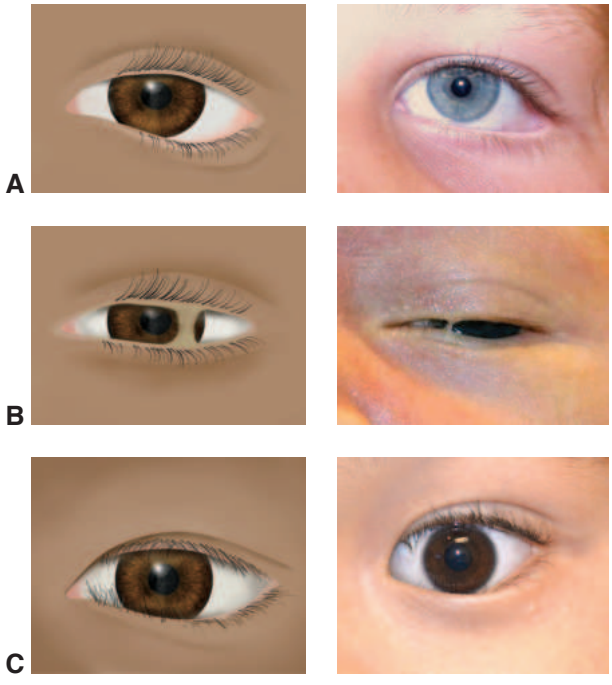

Figure 10-4 Congenital eyelid deformities. **A,** Euryblepharon. **B,** Ankyloblepharon. **C,** Epiblepharon. *(Illustration by Cat N. Burkat, MD. Part A courtesy of Jill Foster, MD; part B courtesy of William Katowitz, MD; part C courtesy of Bradford W. Lee, MD, MSc.)*

Epiblepharon

Epiblepharon is most common in children of Asian or Hispanic heritage. In this condition, the lower eyelid pretarsal muscle and skin ride above the lower eyelid margin to form a horizontal fold of tissue, causing the cilia to assume a vertical position (Fig 10-4C). Pathophysiologically, this condition results from a deficiency in the attachment of the lower eyelid retractors (capsulopalpebral fascia) to the skin. The cilia often do not touch the cornea except in downgaze, and this rarely causes corneal staining. Epiblepharon may not require surgical treatment, because it tends to diminish with the maturation of the facial bones. However, it occasionally results in acute or chronic corneal epithelial irritation; in that case, a repair is performed by excision of the excess skin and pretarsal orbicularis muscle with or without placement of marginal rotation sutures.

Woo KI, Kim YD. Management of epiblepharon: state of the art. *Curr Opin Ophthalmol.* 2016;27(5):433–438.

Epicanthus

Epicanthus is a medial canthal fold that may result from immature midfacial bones or a fold of skin and subcutaneous tissue. The condition is usually bilateral, and an affected child may appear esotropic because of decreased scleral exposure nasally *(pseudostrabismus)*. Traditionally, 4 types of epicanthus have been described (Fig 10-5):

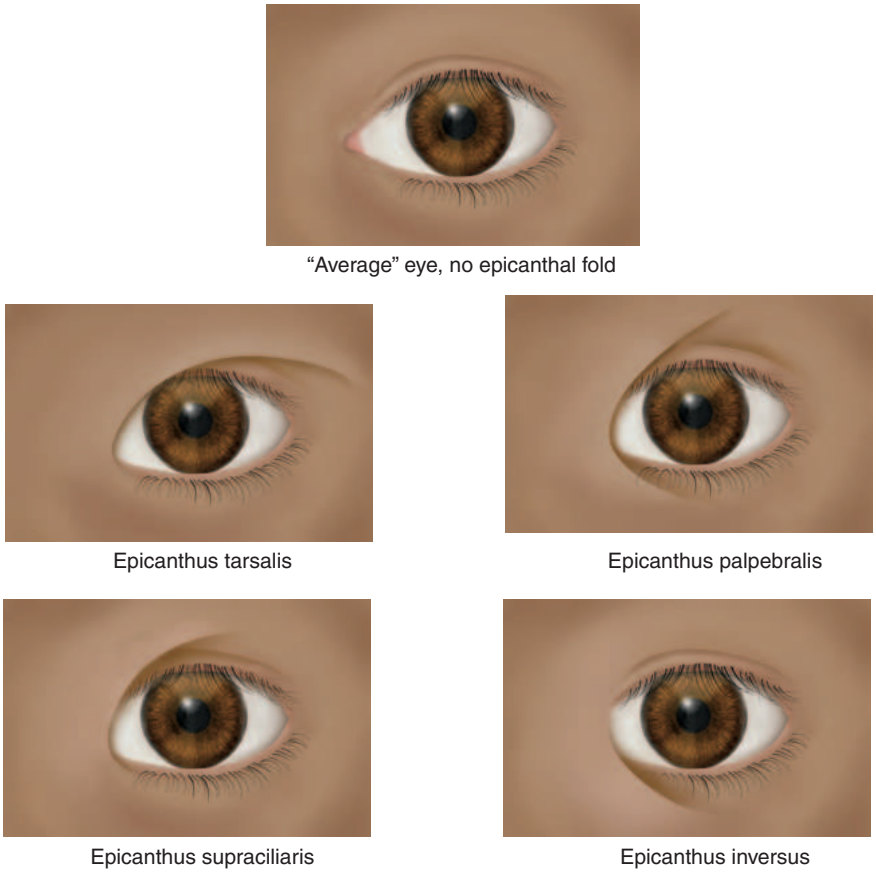

Figure 10-5 Types of epicanthus. **A,** No epicanthal fold. **B,** Epicanthus tarsalis. **C,** Epicanthus inversus. **D,** Epicanthus palpebralis. **E,** Epicanthus supraciliaris. *(Illustration by Cyndie C. H. Wooley.)*

- *epicanthus tarsalis,* in which the fold is most prominent in the upper eyelid
- *epicanthus inversus,* in which the fold is most prominent in the lower eyelid
- *epicanthus palpebralis,* in which the fold involves the upper and lower eyelids equally
- *epicanthus supraciliaris,* in which the fold extends from the eyebrow region to the lacrimal sac

Epicanthus tarsalis can be a normal variation of the Asian eyelid (Fig 10-6), whereas epicanthus inversus is often associated with BPES (see Fig 10-1).

Most forms of epicanthus become less apparent with normal growth of the facial bones. If no associated eyelid anomalies are present, observation is recommended until the face achieves maturity. Epicanthus inversus, however, rarely resolves with facial growth. Most cases of isolated epicanthus requiring treatment are corrected by soft-tissue revisions such as Z-plasty or Y–V-plasty (Fig 10-7). Epicanthus tarsalis in a patient of Asian heritage may be eliminated by a Y–V-plasty with or without the formation of an upper eyelid crease.

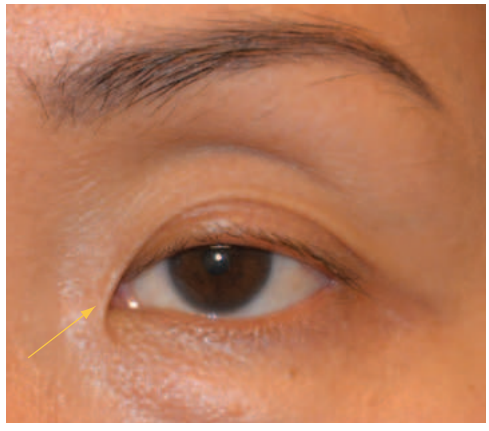

Figure 10-6 Epicanthus tarsalis *(arrow)* in patient with Asian heritage. *(Courtesy of Bradford W. Lee, MD, MSc.)*

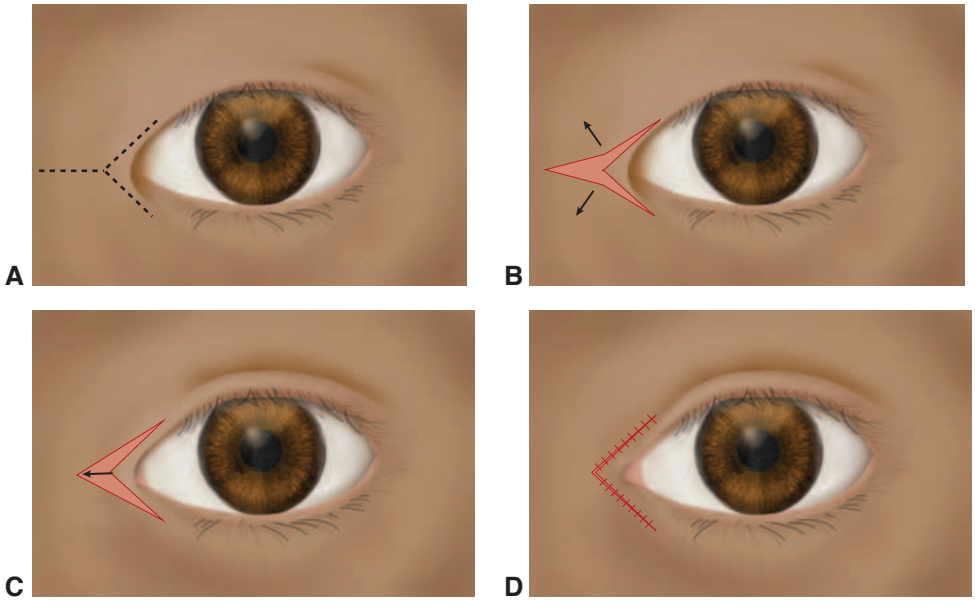

Figure 10-7 Epicanthus tarsalis Y-to-V repair. **A,** The letter "Y" is marked on the skin, with the stem placed horizontally in line with the medial canthal angle. The arms of the Y are marked along the edge of the epicanthal fold. **B,** The markings are incised and the shaded area undermined, which allows the tissue on both sides of the stem to recess into a "V" configuration. **C,** The skin at the center of the Y is advanced medially to meet the bottom of the stem. **D,** Final closure as a V shortens the epicanthal skin fold and exposes medial sclera. *(Illustration by Cyndie C. H. Wooley.)*

Congenital Entropion

In contrast to epiblepharon, eyelid margin inversion is present in congenital entropion. Developmental factors that lead to this rare condition include lower eyelid retractor dysgenesis, structural defects in the tarsal plate, and relative shortening of the posterior lamella. Unlike epiblepharon, congenital entropion is unlikely to improve spontaneously and may require surgical correction. Congenital entropion may be repaired by removing a small amount of the skin and orbicularis muscle along the subciliary portion of the

eyelid, advancing the lower eyelid retractors to the tarsus, and lengthening the posterior lamella.

Congenital tarsal kink

A tarsal kink (Fig 10-8) is an unusual form of congenital entropion in which the upper eyelid tarsal plate is folded, resulting in entropion. There is typically an absent eyelid crease and a corneal opacity or infiltrate may be present as well. It may be repaired by removal of the kink and/or tarsotomy with marginal rotation. In some cases, skin grafting for the anterior lamella may be necessary.

Congenital Distichiasis

Distichiasis is a rare, sometimes hereditary condition in which an extra row of eyelashes is present in place of the meibomian gland orifices. Congenital distichiasis occurs when embryonic pilosebaceous units improperly differentiate into hair follicles (Fig 10-9). Treatment is indicated if the patient is symptomatic or if keratopathy develops. Lubricants and soft contact lenses may be sufficient; if not, electrolysis, radiofrequency ablation, and eyelid splitting with the removal of the follicles are alternatives. Cryoepilation is used less often because of the risk of eyelid margin thinning or notching, eyelash loss, and skin hypopigmentation.

Congenital Coloboma

A *coloboma* is an embryologic cleft that is usually an isolated anomaly when it occurs in the medial upper eyelid. A true coloboma includes a defect in the eyelid margin (Fig 10-10). When located in the lower eyelid, however, a coloboma is frequently associated with other congenital conditions such as facial clefts (eg, Goldenhar syndrome) and lacrimal deformities.

Full-thickness defects affecting up to one-third of the eyelid can usually be repaired by creating raw vertical margins and sliding flaps along the eyelid crease. A lateral cantholysis

Figure 10-9 Congenital distichiasis *(arrow). (Courtesy of Jill Foster, MD.)*

Figure 10-10 Eyelid coloboma of the left upper eyelid in a patient with oculo-auriculo-vertebral spectrum (Goldenhar syndrome). *(Courtesy of Nahyoung Grace Lee, MD.)*

may provide additional horizontal relaxation. Almost all large defects can be repaired with the use of a variation of the lateral canthal semicircular flap technique (see Chapter 11 in this volume). Because of the risk of amblyopia, eyelid-sharing procedures that occlude the visual axis are avoided unless no other reconstructive options are possible.

Cryptophthalmos

Cryptophthalmos is a rare condition that presents with partial or complete absence of the eyebrow, palpebral fissure, eyelashes, and conjunctiva (Fig 10-11). The partially developed adnexa are fused to the anterior segment of the globe. Cryptophthalmos may be unilateral or bilateral. Histologically, the orbicularis oculi, levator muscle, tarsus, conjunctiva, and meibomian glands are attenuated or absent; thus, attempts at reconstruction are difficult. Severe ocular defects are present in the underlying eye, which can be microphthalmic or associated with an orbital cyst.

Congenital Eyelid Lesions: Infantile Hemangioma

Although infantile hemangiomas (formerly known as capillary hemangiomas) sometimes occur as congenital eyelid lesions, most are not apparent at birth. In the typical natural course, the lesion usually develops within a few weeks or months after birth, increases in size over the first year, and gradually involutes during the next 3–7 years. Hemangiomas may also involve the orbit (see the section Vascular Tumors, Malformations, and Fistulas in Chapter 5 of this volume).

Management

Hemangiomas are associated with a high incidence of amblyopia; therefore, treatment is recommended for patients who present with occlusion of the visual axis, anisometropia, or strabismus, as well as for lesions causing significant disfigurement. Lesions limited to the eyelid may be treated with topical timolol gel or intralesional steroids. Topical timolol gel appears to have minimal adverse effects. If vision is threatened or if there is more widespread or deeper orbital involvement, systemic propranolol or oral corticosteroids are typically required.

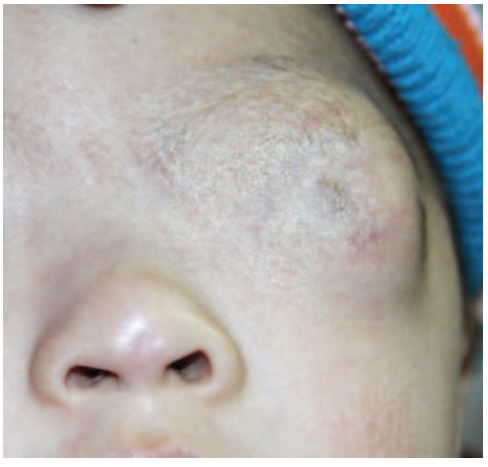

Figure 10-11 Complete cryptophthalmos. *(Courtesy of Cat N. Burkat, MD.)*

For patients who cannot take β-blockers or do not respond to timolol, intralesional steroids are considered. Intralesional steroids, which may act by rendering the tumor's vascular bed more sensitive to the body's circulating catecholamines, are relatively safe and effective. However, rare cases of eyelid necrosis, fat atrophy, embolic retinal vascular occlusion, and systemic adrenal suppression may occur after even a single injection. Although treatment with systemic steroids eliminates the risks of eyelid necrosis and vascular emboli, the dosage and risk of systemic adverse effects are increased.

Other treatment options may be considered for vision-compromising lesions that persist despite intervention. Topical treatment with clobetasol propionate has been reported to successfully shrink eyelid hemangiomas. Compared with oral or intralesional steroids, the topical route reduces, although does not eliminate, the risk of systemic exposure. Interferon-alfa is reserved for life-threatening or sight-threatening lesions unresponsive to other forms of treatment because of the risk of serious adverse effects. Surgical excision may be used for rare well-circumscribed lesions, but it requires meticulous control of hemostasis. The use of a carbon dioxide laser as an incisional device helps control bleeding during the removal of a lesion. Vascular lasers, such as the pulsed dye laser, may be used on the superficial (1–2 mm) layers of the skin to diminish the redness of a lesion, but they do not penetrate deeply enough to shrink a visually disabling lesion.

Acquired Eyelid Disorders

Chalazion

A chalazion is a focal, painless nodule on the eyelid that results from obstructed sebaceous glands (meibomian glands or glands of Zeis; Fig 10-12). This common disorder occurs in all age groups, is caused by lipogranulomatous inflammation visible on histology, and is often associated with conditions such as rosacea and chronic blepharitis.

The *meibomian glands* are oil-producing sebaceous glands located in the tarsal plate. The oil is an essential component of the tear film. If the gland orifices on the eyelid margin

Figure 10-12 Chalazion on the right upper eyelid. *(Courtesy of Nahyoung Grace Lee, MD.)*

become plugged, the contents of the glands *(sebum)* accumulate within the tarsus causing an inflammatory reaction.

Management

In the acute inflammatory phase, the primary treatment consists of warm compresses applied several times per day and appropriate eyelid hygiene, which can consist of eyelid wipes, scrubs, or cleansing using baby shampoo, tea tree oil cleanser, or hypochlorous acid. Topical antibiotic eyedrops or ointments may be helpful in cases of significant blepharitis. In complex or recurrent cases, oral doxycycline or azithromycin may be considered because of their ability to modulate the expression of inflammatory mediators (matrix metalloproteinases, collagen production, interleukin-1, nitric oxide, and activated B cells), inhibiting bacterial lipase production and thereby improving the tear film balance. Tetracyclines are contraindicated in children and during pregnancy and may be associated with allergy, gastrointestinal distress, photosensitivity, and drug resistance.

Chronic, persistent chalazia that have failed conservative management may require surgery or an intralesional injection for resolution. For surgical management, when the greatest inflammatory response is on the posterior eyelid, a chalazion clamp is applied, the eyelid is everted, and an 11 blade can be used to make a vertical incision through the tarsal plate. A curette is used to remove the lipogranulomatous material, and the pseudocapsule can be sharply excised (Fig 10-13, Video 10-1). Caution is required when inflammatory tissue is removed at the eyelid margin or adjacent to the punctum. In rare cases, the inflammatory response is more severe on the anterior eyelid; in such cases, a skin incision is used. Given the risk of masquerade conditions, including sebaceous carcinoma that can mimic a chronic, recurrent chalazion, pathologic examination is appropriate for atypical or recurrent chalazia.

VIDEO 10-1 Incision and drainage of chalazion, upper eyelid. *Courtesy of Richard C. Allen, MD, PhD.*

Intralesional injection of corticosteroids is a nonsurgical treatment for chalazia that have failed conservative management. However, intralesional steroid injections carry the

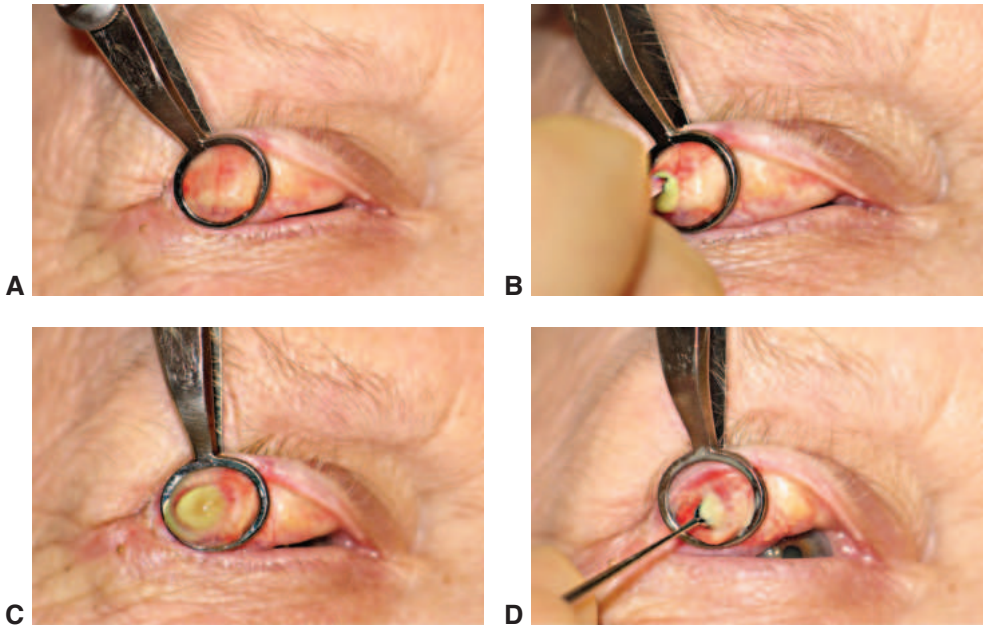

Figure 10-13 Incision and curettage of chalazion. **A,** The chalazion clamp is centered over the lesion and the eyelid everted. **B,** A number 11 blade scalpel is used to incise the tarsus vertically, stopping several millimeters from the eyelid margin. **C,** Lipogranulomatous material is drained. **D,** A curette can further remove the contents and excess fibrotic tissue or pseudocapsule can be excised. *(Courtesy of Cat N. Burkat, MD.)*

risk of skin depigmentation, dermal atrophy, fat atrophy, and intra-arterial embolism that can rarely lead to central retinal artery occlusion and vision loss. The combination of excision and steroid injection yields a 95% resolution rate.

Wladis EJ, Bradley EA, Bilyk JR, Yen MT, Mawn LA. Oral antibiotics for meibomian gland-related ocular surface disease: a report by the American Academy of Ophthalmology. *Ophthalmology*. 2016;123(3):492–496.

Hordeolum

A hordeolum is an acute infection (usually staphylococcal) associated with obstructed sebaceous glands in the eyelid. It presents as an erythematous, tender nodule and is often associated with eyelid edema, superficial skin exfoliation, crusting, or even cellulitis or abscess formation. It can have a whitish appearance like a pimple filled with purulent material. It can involve the glands of Zeis *(external hordeolum,* or *stye)* at the eyelid margin or the meibomian glands *(internal hordeolum)* within the tarsus. In the case of external hordeola, the infection may appear to center around an eyelash follicle, and the eyelash can be epilated to promote drainage (Fig 10-14). Like chalazia, most hordeola resolve spontaneously, but the diligent application of hot compresses and topical antibiotic ointment may be helpful. Systemic antibiotics such as doxycycline that cover staphylococcal infections are indicated in cases with associated cellulitis, abscess, or diffuse inflammation. Surgical

drainage of a pointing hordeolum or abscess may be required; this can accelerate resolution and allow culturing of the purulent material.

Eyelid Edema

Eyelid edema can be caused by local conditions, such as insect bites or allergy (Fig 10-15); systemic conditions such as cardiovascular disease, renal disease, thyroid eye disease, and collagen vascular disease; or other inflammatory or neoplastic orbital conditions, such as lymphoma. Cerebrospinal fluid leakage into the orbit and eyelids after trauma may mimic eyelid edema. Lymphedema may occur if the lymphatic drainage system from the eyelid is disrupted, such as after extensive lymph node dissection of the neck (Fig 10-16).

Floppy Eyelid Syndrome

Floppy eyelid syndrome is characterized by ocular irritation, redness, eyelash ptosis, loss of eyelash parallelism, and mild mucus discharge that is frequently worse on awakening (Fig 10-17). Patients have chronic papillary conjunctivitis and a superior tarsal plate that is rubbery and easily everted. Histologic examination has demonstrated a marked decrease in the number of elastin fibers within the tarsus. During an examination, the lax upper eyelid everts spontaneously, especially laterally, when pulled up toward the forehead. Patients often report sleeping in a prone position, which can cause mechanical upper eyelid eversion, with the superior palpebral conjunctiva rubbing against the pillow or bedding. Associations have been reported with obesity, obstructive sleep apnea, keratoconus, eyelid rubbing, and hyperglycemia. Sleep studies are recommended to rule out sleep apnea.

Initial conservative treatment consists of viscous lubrication and a patch or shield at night. If warranted, surgical correction, which consists of wedge resection and horizontal eyelid tightening, can be undertaken. If the patient has been diagnosed with sleep apnea, the use of a continuous positive airway pressure device may reduce prone position sleeping and minimize recurrence after surgical correction.

Eyelid Imbrication Syndrome

Eyelid imbrication syndrome occurs when a lax upper eyelid with a normal tarsal plate overrides the lower eyelid margin during closure; this results in chronic mechanical conjunctivitis.

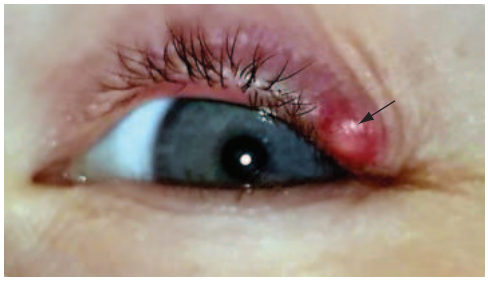

Figure 10-14 Hordeolum of the left upper eyelid *(arrow)*. *(Courtesy of Cat N. Burkat, MD.)*

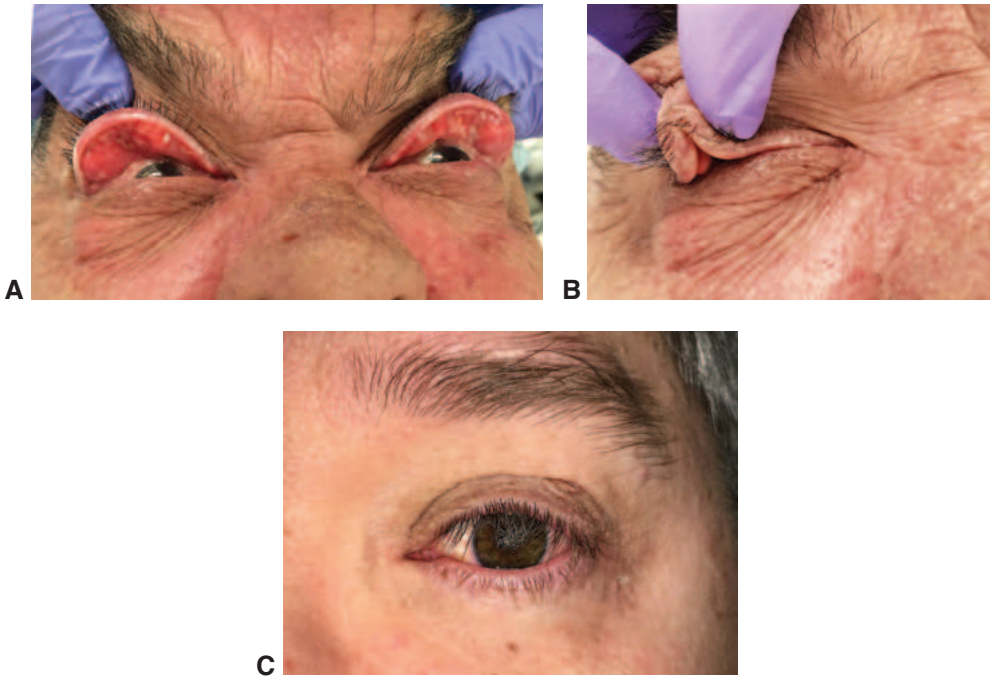

Figure 10-17 Floppy eyelid syndrome. **A,** Easily everted upper eyelids with inflamed tarsal conjunctiva and papillary reaction**. B,** Flaccid upper eyelid tone. **C,** Eyelash ptosis. *(Courtesy of Cat N. Burkat, MD.)*

Management consists of topical lubrication in mild cases. In more severe cases, horizontal tightening of the upper eyelid is indicated.

Trichotillomania

Trichotillomania is an impulse-control disorder most commonly seen in preteen or teenaged girls. It is characterized by the repeated desire to pull out hairs, frequently eyebrow cilia

Figure 10-18 Trichotillomania, with characteristic finding of eyelashes of multiple different lengths. *(Courtesy of Cat N. Burkat, MD.)*

or eyelashes. Diagnosis may be elusive because affected patients usually deny the behavior; therefore, parental counseling or psychiatric consultation may be indicated. Characteristically, multiple hairs are broken off and regrow at different lengths, a finding that guides the diagnosis (Fig 10-18).

Eyelid Neoplasms

Numerous benign and malignant cutaneous neoplasms can develop in the periocular skin, arising from the epidermis, dermis, or eyelid adnexal structures. Most lesions, whether benign or malignant, develop from the epidermis, the rapidly growing superficial layer of the skin. Although many of these lesions also occur elsewhere on the body, their appearance and behavior in the eyelids may be unique because of the particular characteristics of eyelid skin and the specialized adnexal elements. The malignant lesions that most frequently affect the eyelids are basal cell carcinoma, squamous cell carcinoma, sebaceous cell carcinoma, and melanoma. Histologic examination of suspected cutaneous malignancies is recommended.

Clinical Evaluation of Eyelid Tumors

The history and physical examination of eyelid lesions offer important clues regarding the likelihood of malignancy. Predisposing factors in the development of skin cancer include

- a history of prior skin cancer
- excessive sun exposure, especially blistering sunburn
- previous radiation therapy
- a history of smoking
- Celtic or Scandinavian ancestry, with fair skin, red hair, and blue eyes
- immunosuppression

Signs suggesting malignancy are

- ulceration or chronic, nonhealing lesion
- bleeding, crusting, drainage
- destruction of normal eyelid margin architecture (especially meibomian orifices)

- loss of cilia *(madarosis)*
- heaped-up, pearly, translucent margins with central ulceration
- fine telangiectasias
- pigmentary changes
- loss of fine cutaneous wrinkles or vellus hair

Lesions near the puncta should be evaluated for punctal or canalicular involvement. Probing and irrigation may be required to exclude lacrimal system involvement or to prepare for surgical reconstruction.

Palpable induration extending beyond visibly apparent margins suggests tumor infiltration into the dermis and subcutaneous tissue. Large lesions should be assessed for evidence of fixation to deeper tissues or bone. In addition, regional lymph nodes should be palpated for evidence of metastases in cases of suspected squamous cell carcinoma, sebaceous cell carcinoma, melanoma, or Merkel cell carcinoma. Lymphatic tumor spread may produce rubbery swelling along the jawline or in front of the ear. Restriction of ocular motility and proptosis suggest orbital extension. Assessment of the function of cranial nerves V and VII can reveal deficiencies that may indicate perineural tumor spread. Perineural invasion is a characteristic of squamous cell carcinoma. Systemic evidence of liver, pulmonary, bone, or neurologic involvement should be sought in cases of sebaceous adenocarcinoma or melanoma of the eyelid. It is important to obtain photographs and measurements before treatment of the lesion.

For more extensive coverage, including additional clinical and pathology photographs, see BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors.*

Benign Eyelid Lesions

Epithelial hyperplasias

The terminology used to describe benign epithelial proliferations, the most common type of benign eyelid lesions, continues to evolve. It is helpful to group these various benign epithelial proliferations under the clinical heading of *papillomas.* (This designation does not necessarily imply any association with the papillomavirus.) Clinical and histologic characterizations of these lesions overlap considerably. Included within this group are seborrheic keratosis, pseudoepitheliomatous hyperplasia, verruca vulgaris (wart), acrochordon (also called skin tag, fibroepithelial polyp, or squamous papilloma; Fig 10-19), basosquamous acanthoma, squamous acanthoma, and many others. All of these benign proliferations can be managed with shave excision at the dermal–epidermal junction.

Seborrheic keratosis (Fig 10-20) is an example of an acquired benign eyelid papilloma that tends to affect middle-aged and senior patients. Its clinical appearance varies; it may be sessile or pedunculated and have varying degrees of pigmentation and hyperkeratosis. On facial skin, seborrheic keratosis typically appears as a smooth, greasy, stuck-on lesion. On the thinner eyelid skin, however, it can be more lobulated, papillary, or pedunculated, with visible excrescences on its surface. These lesions can be managed by shave excision. A seborrheic keratosis involving a hair follicle, called an *inverted follicular keratosis,* may be more elevated and nodular (Fig 10-21) and can be confused with a keratoacanthoma or squamous cell carcinoma.

Figure 10-20 Seborrheic keratoses of the left upper eyelid. *(Courtesy of Bobby S. Korn, MD, PhD.)*

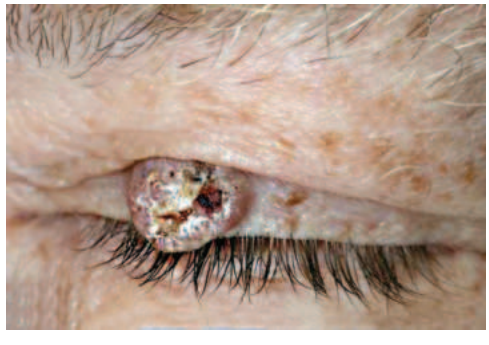

Figure 10-21 Inverted follicular keratosis of the left upper eyelid. *(Courtesy of Cat N. Burkat, MD.)*

Pseudoepitheliomatous hyperplasia is not a discrete lesion but rather a pattern of reactive changes in the epidermis that may develop over areas of inflammation or neoplasia.

Verruca vulgaris (wart), caused by epidermal infection with the human papillomavirus (type 6 or 11), rarely occurs in thin eyelid skin (Fig 10-22). Cryotherapy or excision may eradicate the lesion and minimize the risk of viral spread.

Cutaneous horn is a descriptive, nondiagnostic term referring to *exuberant hyperkeratosis* (Fig 10-23). This lesion may be associated with various benign or malignant histologic processes, including seborrheic keratosis, verruca vulgaris, and squamous or basal cell carcinoma. Biopsy of the base of the cutaneous horn is recommended.

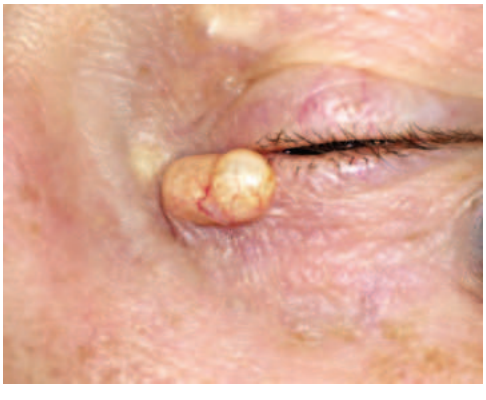

Figure 10-24 Epidermal inclusion cyst of the left lower eyelid. *(Courtesy of Cat N. Burkat, MD.)*

Benign epithelial lesions

After papillomas, cysts of the epidermis are the second most common type of benign periocular cutaneous lesions, accounting for approximately 18% of excised benign lesions. Most of these are *epidermal inclusion cysts,* which arise from the infundibulum of the hair follicle, either spontaneously or after traumatic implantation of epidermal tissue into the dermis (Fig 10-24). The lesions are slow growing, elevated, round, and smooth. They often have

a central pore, indicating the remaining pilar duct. Although these cysts are often called *sebaceous cysts,* they are actually filled with keratin. Rupture of the cyst wall may cause an inflammatory foreign-body reaction. The cysts may also become secondarily infected.

Recommended treatment for small cysts is excision or marsupialization, which involves excising around the periphery of the cyst but leaving the base of the cyst wall to serve as the new surface epithelium. Larger or deeper cysts may require complete excision, in which case the cyst wall should be removed intact to reduce the possibility of recurrence.

Multiple tiny epidermal inclusion cysts are called *milia* (Fig 10-25). They are particularly common in newborn infants. Generally, milia resolve spontaneously, but they may be marsupialized with a sharp blade or needle. Multiple confluent milia may be treated with topical retinoic acid cream.

A less common epidermal cyst is the *pilar,* or *trichilemmal, cyst.* Such cysts are clinically indistinguishable from epidermal inclusion cysts, but they tend to occur in areas containing large and numerous hair follicles. Approximately 90% of pilar cysts occur on the scalp; in the periocular region, they are generally found in the eyebrows. The cysts are filled with desquamated epithelium, and calcification occurs in approximately 25% of cases.

Molluscum contagiosum is a viral infection of the epidermis that often involves the eyelid in children with associated follicular conjunctivitis (Fig 10-26). Occasionally, multiple

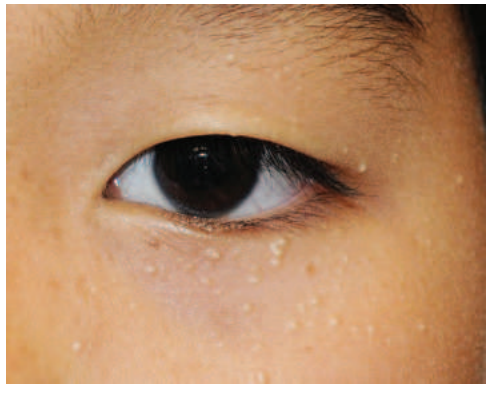

Figure 10-25 Milia of the left upper and lower eyelid. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Figure 10-26 Molluscum contagiosum of the right upper eyelid (*arrow),* which has caused conjunctivitis. *(Courtesy of Steven M. Couch, MD.)*

exuberant lesions appear in adult patients with HIV/AIDS. The lesions are characteristically waxy and nodular, with a central umbilication. They may produce associated follicular conjunctivitis. Treatment is observation, oral cimetidine, excision, controlled cryotherapy, or curettage. Biopsy showing characteristic molluscum bodies on histology can make a definitive diagnosis. (For histologic findings, see BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors.*)

Xanthelasmas are yellowish plaques that occur commonly in the medial canthal areas of the upper and lower eyelids (Fig 10-27). They represent lipid-laden macrophages in the superficial dermis and subdermal tissues. Deep extension into the orbicularis oculi muscle can occur. In rare instances, xanthelasmas are associated with hyperlipidemia or congenital disorders of lipid metabolism, so patients whose lipid levels are unknown may benefit from having them checked by their primary care physician. When excising these lesions, the surgeon must be careful to avoid causing cicatricial ectropion or eyelid retraction. Other treatment options include serial excision, laser ablation, and topical trichloroacetic acid. Xanthelasmas may commonly recur after excision.

Benign Adnexal Lesions

In this context, the term *adnexa* refers to skin appendages that are located within the dermis but communicate through the epidermis to the surface. They include oil glands, sweat glands, and hair follicles. The eyelids contain both the specialized eyelashes and the normal vellus hairs found on the skin throughout the body. Periocular adnexal oil glands include

- the *meibomian glands* within the tarsal plate
- the *glands of Zeis,* associated with eyelash follicles
- normal *sebaceous glands* that are present as part of the pilosebaceous units in the skin hair

Sweat glands in the periocular region include the *eccrine sweat glands,* which have a general distribution throughout the body and are responsible for thermal regulation, and the ciliary glands with apocrine secretion (the *glands of Moll*), which are located in the eyelid margin.

Lesions of oil gland origin

Chalazion and hordeolum These common eyelid lesions are discussed earlier in this chapter in the section Acquired Eyelid Disorders.

Figure 10-27 Xanthelasmas of the upper and lower eyelids. *(Courtesy of Cat N. Burkat, MD.)*

Sebaceous hyperplasia Sebaceous hyperplasia presents as multiple flesh-colored or faintly yellow papules that may have central umbilication (Fig 10-28). They tend to occur on the forehead and cheeks and are common in patients older than 40 years. These lesions are sometimes mistaken for basal cell carcinoma because they may have central umbilication and fine telangiectasias.

Sebaceous adenoma This is a rare tumor that appears as a yellowish papule on the face, scalp, or trunk and may mimic a basal cell carcinoma or seborrheic keratosis (Fig 10-29). Patients with multiple acquired sebaceous gland adenomas, adenomatoid sebaceous hyperplasia, or basal cell carcinomas with sebaceous differentiation have an increased incidence of visceral malignancy *(Muir-Torre syndrome [MTS])* and should be evaluated accordingly.

Tumors of eccrine sweat gland origin

Eccrine hidrocystoma Eccrine hidrocystomas are common cystic lesions 1–3 mm in diameter that occur in groups and tend to cluster around the lower eyelids and canthi and on the face (Fig 10-30). They are considered to be ductal retention cysts, and they often enlarge in conditions such as heat and increased humidity, which stimulates perspiration. Treatment consists of surgical excision.

Syringoma Syringomas are benign eccrine sweat gland tumors found commonly in female adolescents and adults. They present as multiple small, waxy nodules 1–2 mm in

Figure 10-28 Sebaceous hyperplasia of the right lower eyelid. *(Courtesy of Cat N. Burkat, MD.)*

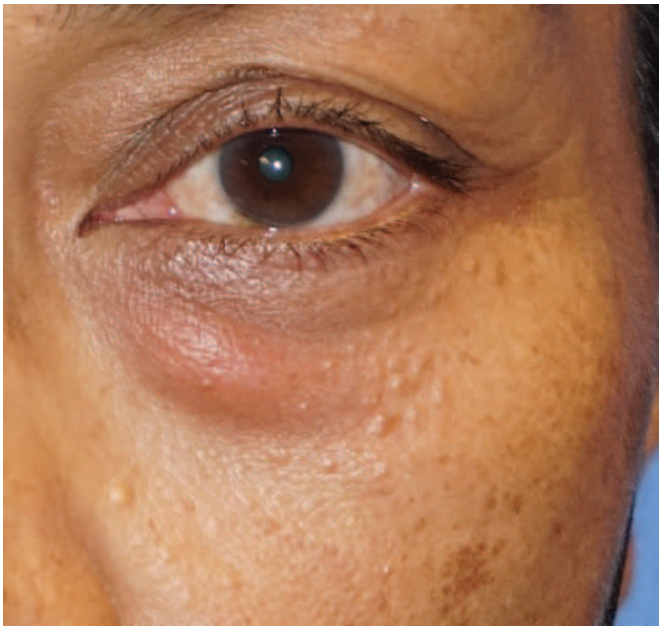

Figure 10-31 Syringomas of the left lower eyelid. *(Courtesy of Bradford W. Lee, MD, MSc.)*

diameter and are most common on the lower eyelids, although the upper eyelids can be involved as well (Fig 10-31). Syringomas can also be found elsewhere on the body, such as in the axilla and sternal regions. They become more apparent during puberty. Because the eccrine glands are located within the dermis, these lesions are too deep to allow shave excision. They can be surgically excised or treated with ablative dermatological lasers.

A less common variant, *chondroid syringoma,* occurs most commonly in middle-aged men and can enlarge to 3 cm. It is composed of sweat gland components within a mixed cartilaginous stroma.

Pleomorphic adenoma This rare benign tumor occurs most commonly in the head and neck region and may involve the eyelids (Fig 10-32). Histologically, the tumor is identical to pleomorphic adenoma of the salivary and lacrimal glands (discussed in Chapter 5). Treatment is complete surgical excision.

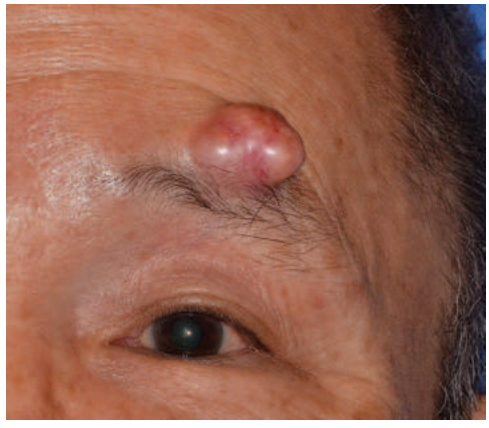

Figure 10-32 Pleomorphic adenoma (benign mixed tumor) of the left eyebrow. *(Courtesy of Bobby S. Korn, MD, PhD.)*

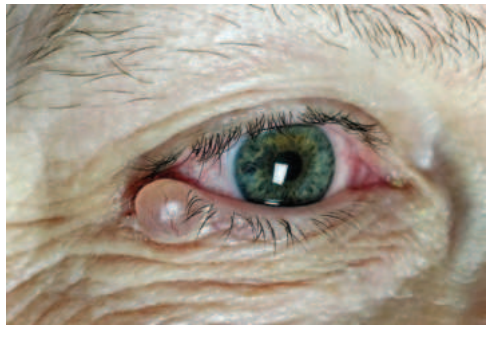

Figure 10-33 Apocrine hidrocystoma of the right lower eyelid. *(Courtesy of Cat N. Burkat, MD.)*

Tumors of apocrine sweat gland origin

Apocrine hidrocystoma A very common, smooth cyst arising from the glands of Moll along the eyelid margin, apocrine hidrocystoma is considered to be an adenoma of the secretory cells of Moll rather than a retention cyst (Fig 10-33). These lesions are typically translucent or bluish and they transilluminate. There may be multiple cysts and often extend deep beneath the surface, especially in the canthal regions. Treatment for superficial cysts is marsupialization. Deep cysts require complete excision of the cyst wall.

Cylindroma Cylindromas *(eccrine spiradenomas)* are rare tumors that can be solitary or multiple and may be dominantly inherited. Lesions are dome-shaped, smooth, flesh-colored nodules of varying sizes that tend to affect the scalp and face (Fig 10-34). They may occur so profusely in the scalp that it is entirely covered with lesions, in which case they are called *turban tumors.* Treatment is surgical excision, which may be difficult if multiple lesions involve a large surface area.

Tumors of hair follicle origin

Several rare benign lesions may arise from the eyelashes, eyebrows, or vellus hairs in the periocular region.

Trichoepithelioma These lesions are small, flesh-colored papules with occasional telangiectasias that occur on the eyelids (Fig 10-35A) or forehead. Histologically, trichoepitheliomas

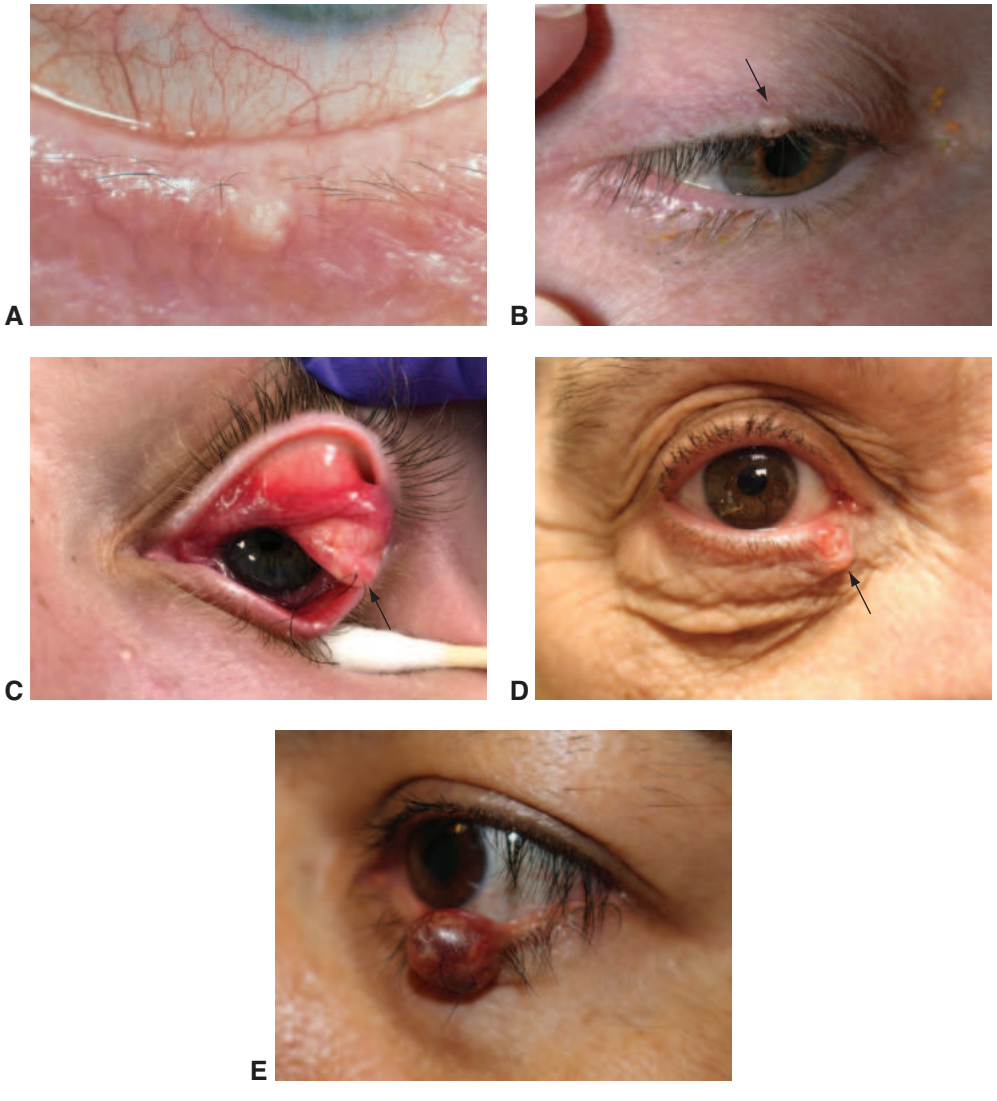

Figure 10-35 Tumors arising from the hair follicles. **A,** Trichoepithelioma. **B,** Trichoadenoma *(arrow)*. **C,** Trichofolliculoma of the palpebral conjunctiva *(arrow)*. **D,** Trichilemmoma *(arrow)*. **E,** Pilomatricoma. *(Part A courtesy of Jeffrey A. Nerad, MD; parts B, D, and E courtesy of Nahyoung Grace Lee, MD; part C courtesy of Cat N. Burkat, MD.)*

appear as basaloid islands and keratin cysts with immature hair follicle structures. If keratin is abundant, these lesions may clinically resemble an epidermal inclusion cyst. The individual histologic picture may be difficult to differentiate from that of basal cell carcinoma. Simple excision is curative.

Trichoadenoma A trichoadenoma is a benign, slow-growing tumor of the hair follicle that consists of multiple keratin-filled cysts and can sometimes appear like a basal cell carcinoma (Fig 10-35B).

Trichofolliculoma A trichofolliculoma is a single, sometimes umbilicated lesion found mainly in adults. Histologically, it represents a squamous cystic structure containing keratin and hair shaft components (Fig 10-35C).

Trichilemmoma Another type of solitary lesion that occurs predominantly in adults, trichilemmomas resemble verrucae (Fig 10-35D). Histologically, they show glycogen-rich cells oriented around hair follicles.

Pilomatricoma Also known as *pilomatrixoma,* this lesion most often affects children and young adults. It usually occurs in the eyebrow and central upper eyelid as a nontender, reddish-purple, subcutaneous mass attached to the overlying skin (Fig 10-35E). Pilomatricomas may become quite large, measuring up to 5 cm or more. The tumor is composed of islands of epithelial cells surrounded by basophilic cells with shadow cells. Multiple lesions or familial cases may be associated with Gardner syndrome, familial adenomatous polyposis, Turner syndrome, myotonic dystrophy, and Rubinstein-Taybi syndrome. Excision is usually curative, and recurrence is rare.

Benign Melanocytic Lesions

Melanocytic lesions of the skin arise from 3 sources: nevus cells, dermal melanocytes, and epidermal melanocytes. Virtually any benign or malignant lesion may be pigmented, and lesions of melanocytic origin do not necessarily have visible pigmentation. For example, seborrheic keratoses are frequently pigmented, and basal cell carcinomas are occasionally pigmented, especially if they arise in persons with darker skin. In contrast, dermal nevi typically have no pigmentation in White individuals. Melanocytes are normally found distributed at the dermal–epidermal junction throughout the skin. Nevus cells are similar to melanocytes in that both produce melanin; however, nevus cells are arranged in clusters and nests and lack dendritic processes (except for blue nevus cells). Both nevus cells and melanocytes give rise to several types of benign lesions (Table 10-1). In addition to the individual lesions described in the following paragraphs, diffuse eyelid and facial skin hyperpigmentation called *melasma,* or *chloasma,* can occur in women who are pregnant or using oral contraceptives; in families with an autosomal dominant trait; and in patients with chronic atopic eczema, rosacea, and other inflammatory dermatoses.

Nevi

Nevi are the third most common benign lesions encountered in the periocular region (after papillomas and epidermal inclusion cysts). They arise from *nevus cells,* which are

Table 10-1 Melanocytic Skin Lesions of the Face

Benign Melanocytic Lesions	Premalignant Melanocytic Lesions	Malignant Melanocytic Lesions
Nevi	Lentigo maligna	Cutaneous melanoma:

grouped as clusters in the basal epidermis and dermis and in the junction zone between these 2 layers. Nevi are not apparent clinically at birth but begin to appear during childhood and often develop increased pigmentation during puberty.

Over the course of a person's lifetime, nevi evolve through 3 stages: (1) *junctional* (located in the basal layer of the epidermis at the dermal–epidermal junction), (2) *compound* (extending from the junctional zone up into the epidermis and down into the dermis), and (3) *intradermal* (caused by involution of the epidermal component and persistence of the dermal component). In children, nevi arise initially as junctional nevi, which are typically flat, pigmented macules. Beyond the second decade of a person's life, most nevi become compound, at which stage they appear as elevated, pigmented papules. Later in life, the pigmentation is lost, and the compound nevus remains as a minimally pigmented or amelanotic lesion (Fig 10-36). By the time a person is 70 years, virtually all nevi have become intradermal nevi and have lost pigmentation. For histology illustrating the 3 stages of nevi, see BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors*.

Nevi are frequently found on the eyelid margin and often mold to the ocular surface (Fig 10-37). Asymptomatic benign nevi require no treatment, but malignant transformation

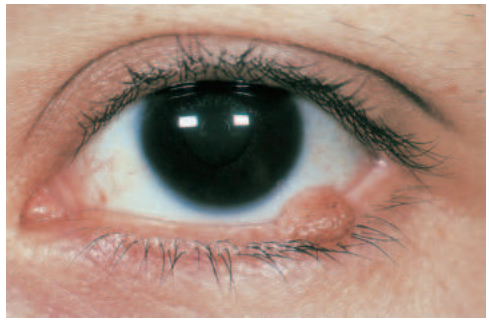

Figure 10-37 Left lower eyelid margin nevus molding to the globe.

Figure 10-38 Kissing nevus of the right upper and lower eyelids. *(Courtesy of Bobby S. Korn, MD, PhD.)*

of a junctional or compound nevus can occur in rare cases. Nevi can also involve both the upper and lower eyelid margins (*kissing nevus,* Fig 10-38). Nevi may become symptomatic if they rub on the ocular surface or enlarge and obstruct vision or lacrimal outflow. When amelanotic, they can be confused with basal cell tumors. They are managed with shave excision or wedge resection.

Ephelis (freckle)

An *ephelis,* or *freckle,* is a small, flat, brown spot that can occur on various areas of the body and facial skin, including malar areas, nose, eyelids, or the conjunctiva (Fig 10-39A). Ephelides arise from hyperpigmentation of the basal layer of the epidermis. Although the number of epidermal melanocytes is not increased, they extrude more than the usual amount of pigment into the epidermal basal cell layer. Ephelides are common in fair-skinned persons, and the hue of the ephelis darkens with sunlight exposure. No treatment is necessary other than sun protection.

Lentigo simplex

Simple lentigines are flat, pigmented spots that are larger in diameter than ephelides (Fig 10-39B). Lentigo simplex can occur at any age and is not related to sun exposure. The condition also differs from ephelides in that the number of epidermal melanocytes is increased, and melanin is found in adjacent basal keratinocytes. Individual lesions are

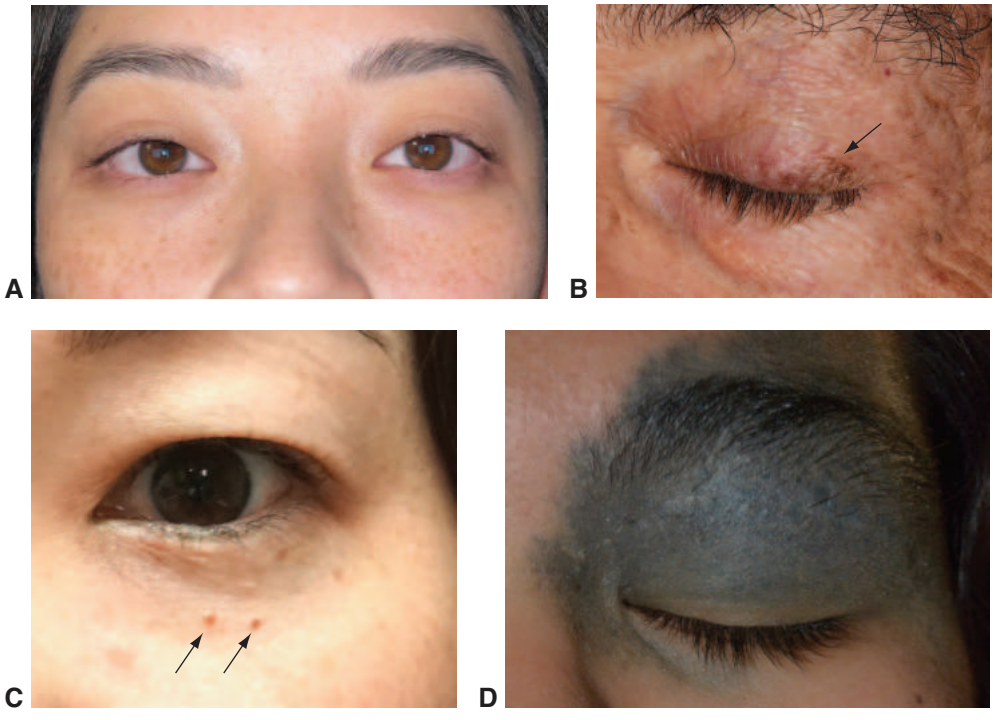

Figure 10-39 Benign melanocytic lesions. **A,** Ephelis. **B,** Lentigo simplex *(arrow)*. **C,** Solar lentigo *(arrows)*. **D,** Blue nevus. *(Part A courtesy of Ann Q. Tran, MD; part B courtesy of Bobby S. Korn, MD, PhD; part C courtesy of Bradford W. Lee, MD, MSc; part D courtesy of Don O. Kikkawa, MD.)*

evenly pigmented and measure a few millimeters in diameter. Eyelid lentigines may be associated with *Peutz-Jeghers syndrome (autosomal dominant polyposis of the intestinal tract)*. No treatment is necessary; however, melanin-bleaching topical agents may improve cosmesis.

Solar lentigo

Multiple solar lentigines may occur in older persons, in which case they are called *age-related lentigo* (Fig 10-39C). Chronic sun exposure produces pigmented macules with an increased number of melanocytes. Solar lentigines are uniformly hyperpigmented and somewhat larger than simple lentigines. The dorsum of the hands and the forehead are the most frequently affected areas. No treatment is necessary, but sun protection is recommended. Melanin-bleaching preparations, intense pulsed-light treatment, picosecond lasers, or cryotherapy may help fade the pigmentation of solar lentigines.

Blue nevi

Blue nevi are dark blue-gray to blue-black, slightly elevated lesions that may be congenital or may develop during childhood (Fig 10-39D). They arise from a localized proliferation of dermal melanocytes. The dark, dome-shaped lesions beneath the epidermis are usually 10 mm or less in diameter. Although their malignant potential is extremely low, these lesions are generally excised.

Oculodermal melanocytosis

Also known as *nevus of Ota,* this diffuse, congenital blue nevus of the periocular skin most often affects persons of African, Hispanic, or Asian descent, especially females. Dermal melanocytes proliferate in the region of the first and second dermatomes of cranial nerve V. The eyelid skin is diffusely brown, gray, or blue, and pigmentation may extend to the adjacent forehead and temple (Fig 10-40A). Approximately 5% of cases are bilateral. Patchy slate-gray pigmentation can be visible on the conjunctiva, sclera, and uvea, as occurs in two-thirds of affected patients; the condition is known as *oculodermal melanocytosis* (Fig 10-40B). Although cutaneous or ocular malignant transformation may occur, especially in White patients, no prophylactic treatment is recommended. Approximately 0.25% of patients with oculodermal melanocytosis develop a uveal melanoma. Patients should also be monitored for glaucoma because 10% of patients with oculodermal melanocytosis also have glaucoma and pigmentation of the trabecular meshwork.

Premalignant Epidermal Lesions: Actinic Keratosis

Actinic keratosis is the most common precancerous skin lesion. It usually affects fair-skinned persons who are middle aged or older with a history of chronic sun exposure (Fig 10-41). These lesions are typically round, scaly, keratotic plaques that on palpation have the texture of sandpaper. They often develop on the face, head, neck, forearms, and dorsal hands. These lesions are in a state of continual flux, increasing in size and darkening in response to sunlight and remitting with reduced sun exposure. It has been reported that up to 25% of individual actinic keratoses spontaneously resolve over 12 months, although new lesions tend to develop continually. The risk of malignant transformation

Figure 10-40 Oculodermal melanocytosis (nevus of Ota). **A,** Melanocytosis involving the eyelids and temple. **B,** Melanocytosis involving the eyelids, forehead, temple, and sclera. *(Part A courtesy of Cat N. Burkat, MD; part B courtesy of Jill Foster, MD.)*

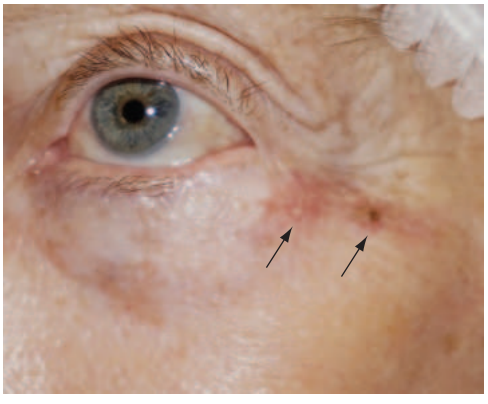

Figure 10-41 Actinic keratoses of the left lateral canthal region. *(Courtesy of Bradford W. Lee, MD, MSc.)*

of an individual actinic keratosis is only 0.24% per year, but during periods of extended follow-up, a person with multiple actinic keratoses has a 12%–20% risk of squamous cell carcinoma developing. Squamous cell carcinomas arising from actinic keratoses are thought to be less aggressive than those developing de novo. For lesions arising in the periocular region, incisional or excisional biopsy is recommended. Widespread lesions may be treated with topical 5-fluorouracil or imiquimod cream, cryotherapy, or photodynamic field therapy.

In Situ Epithelial Malignancies

Squamous cell carcinoma in situ

Squamous cell carcinoma in situ (SCCIS) typically appears as an elevated, nonhealing, erythematous lesion. It may present with scaling, crusting, or pigmented keratotic plaques. Pathologically, the lesions demonstrate full-thickness epidermal atypia without dermal invasion, in contrast to the partial thickness atypia of actinic keratoses. In 5% of patients, SCCIS may progress to vertically invasive squamous cell carcinoma; therefore, complete surgical excision is advised. Alternatively, electrodesiccation and curettage, cryotherapy, and 5-fluorouracil may be used, especially in larger areas of involvement.

Keratoacanthoma

Keratoacanthomas are considered a low-grade subtype of squamous cell carcinoma. The lesion usually begins as a flesh-colored papule on the lower eyelid that develops rapidly into a dome-shaped nodule with a central keratin-filled crater and elevated rolled margins (Fig 10-42). Keratoacanthomas typically occur in individuals who are middle-aged or older, and there is an increased incidence in immunosuppressed patients. Gradual involution over the course of 3–6 months has often been observed. The abundant keratin production in the center of the lesion may incite a surrounding inflammatory reaction, which may play a role in ultimate resolution. At present, incisional biopsy followed by complete surgical excision is recommended. Intralesional methotrexate or 5-fluorouracil may be options for patients who are not surgical candidates.

Figure 10-42 Keratoacanthoma of the right lower eyelid. *(Courtesy of Steven M. Couch, MD.)*

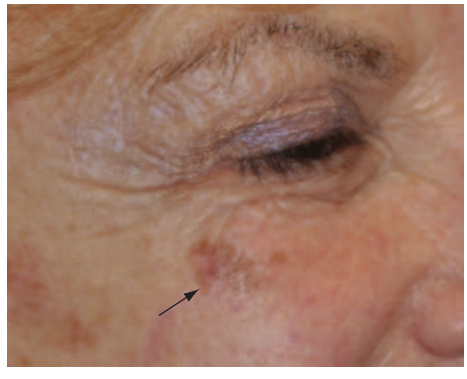

Figure 10-43 Lentigo maligna melanoma of the right cheek. *(Courtesy of Lilangi Ediriwickrema, MD.)*

Premalignant Melanocytic Lesions: Lentigo Maligna

Also known as *Hutchinson melanotic freckle* or *precancerous melanosis,* lentigo maligna is a flat, irregularly shaped, unevenly pigmented, slowly enlarging lesion that typically occurs on the malar region (Fig 10-43). Risk factors include advanced age, lighter skin types, a tendency to develop solar lentigines, and a history of nonmelanoma skin malignancies. A history of intermittent severe sunburns, rather than cumulative sun exposure, is also considered a risk factor for lentigo maligna. Lentigo maligna is characterized by significant pigmentary variation, irregular borders, and progressive enlargement. The malignant melanotic cells are confined to the epidermis but can grow in a radial or intraepidermal pattern and can eventually progress to nodules of vertically invasive lentigo maligna melanoma. The absolute risk of a lentigo maligna melanoma (at any location) after a histologically confirmed lentigo maligna is low, at 2.0%–2.6%.

The area of histologic abnormality frequently extends beyond the visible pigmented borders of the lesion; in the periocular region, cutaneous lentigo maligna of the eyelid may extend onto the conjunctival surface, where the lesion appears identical to primary acquired melanosis. Excision with adequate surgical margins is recommended, with permanent sections for final monitoring. Close observation for recurrence is warranted with photographic documentation.

Malignant Eyelid Tumors

Basal cell carcinoma

Basal cell carcinoma (BCC), the most common eyelid malignancy, accounts for approximately 90%–95% of malignant eyelid tumors. A prospective series of 1295 patients found that BCCs are most often located on the medial canthus (48.3%), lower eyelid (47.5%), and upper eyelid (3.9%). BCCs can have many different clinical manifestations in the eyelid.

Patients at highest risk for BCC are fair-skinned, blue-eyed, red-haired or blond, and middle-aged and older with English, Irish, Scottish, or Scandinavian ancestry. A history of prolonged sun exposure during the first 2 decades of life and a history of cigarette smoking also increase the risk of BCC formation. Patients with prior BCC have a higher probability of additional skin cancers developing. BCC can have a variety of clinical presentations (Fig 10-44) and types, including:

- *Nodular BCC,* which is the most common type and presents as a firm, raised, pearly nodule that may be associated with telangiectasia and central ulceration. Histologically, it shows nests of basal cells originating from the basal layer of the epidermis and may show peripheral palisading. As the nests of atypical cells break through the epidermal surface, central necrosis and ulceration may occur.
- *Morpheaform BCC,* which is less common but more aggressive than nodular BCC. Morpheaform lesions may be firm and slightly elevated with margins that may be indeterminate on clinical examination. Histologically, they show thin cords that radiate peripherally rather than peripheral palisading. The surrounding stroma may show fibrotic proliferation of connective tissue.
- *Multicentric* or *superficial BCC*, which may be mistaken for chronic blepharitis and eyelid margin inflammation. It is frequently associated with madarosis and can silently extend along the eyelid margin.
- *Basosquamous carcinoma,* which is a rare, aggressive neoplasm with characteristics of BCC and squamous cell carcinoma. As compared with BCC, basosquamous carcinoma is more likely to have a local recurrence and lymph node or distant metastases.

BCC is being seen with increasing frequency in younger patients, and the discovery of malignant eyelid lesions in these patients should prompt inquiry into possible systemic associations such as basal cell nevus syndrome or xeroderma pigmentosum:

- *Basal cell nevus syndrome (Gorlin syndrome)* is an autosomal dominant, multisystem disorder characterized by multiple BCCs that can start in the second or third decade of life. It is associated with skeletal abnormalities of the ribs and spine, odontogenic keratocysts (jaw cysts arising from degenerated dental lamina), palmar or plantar pits (punctiform reddish depressions in the skin), calcification of the falx cerebri (seen on X-ray), intestinal hamartomatous polyposis, and a variety of ocular manifestations (Fig 10-45).
- *Xeroderma pigmentosum* is a rare autosomal recessive disorder characterized by extreme sun sensitivity and a defective repair mechanism for UV light–induced DNA damage in skin cells (Fig 10-46).

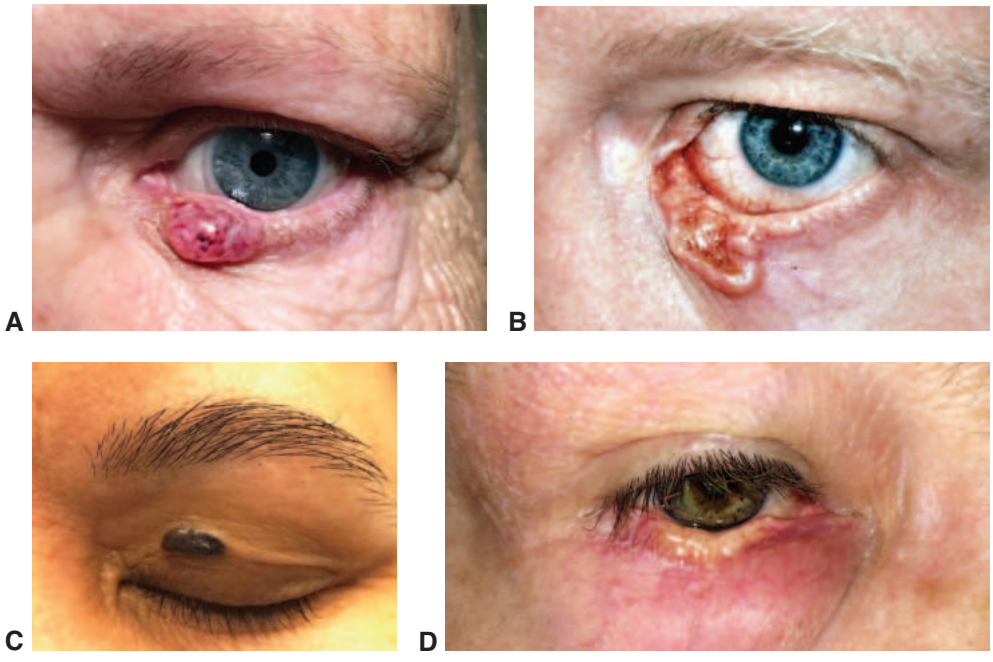

Figure 10-44 Basal cell carcinoma. **A,** Nodular. **B,** Ulcerative. **C,** Pigmented. **D,** Morpheaform. *(Parts A, B, and D courtesy of Cat N. Burkat, MD; part C courtesy of Bradford W. Lee, MD, MSc.)*

Management A biopsy is necessary to confirm any clinical suspicion of BCC (Fig 10-47). The most accurate diagnosis is facilitated by obtaining an incisional biopsy specimen with the following features:

- is representative of the clinically evident lesion
- is large enough for histologic processing
- is not excessively traumatized, cauterized, or crushed
- contains normal tissue at the margin to show the transitional area

The biopsy site should be first photographed because the site often heals so well that the original location can be difficult to find for subsequent tumor removal.

An *incisional biopsy*, in which only a portion of the lesion is biopsied, can be used as a confirmatory procedure if the suspected malignant tumor involves the eyelid margin or medial canthus or is especially large.

An *excisional biopsy* is reasonable when lesions are small and do not involve the eyelid margin or when eyelid margin lesions are away from the lateral canthus or lacrimal punctum. However, histologic monitoring of tumor borders to ensure complete excision is critical. The borders of any excisional biopsy should be marked in case the excision is incomplete and further resection is necessary. Excisional biopsies should be oriented vertically so that closure avoids vertical traction on the eyelid that could lead to eyelid retraction or ectropion. If the margins of the excised portion are positive for residual tumor cells, the involved eyelid area should be excised again, with surgical monitoring of the margins by Mohs micrographic technique or frozen section technique.

Surgery is the treatment of choice for all BCCs of the eyelid. Surgical excision affords the advantages of complete tumor removal with histologic control of the margins. The recurrence rate is lower with excision than with any other treatment modality. Surgical excision also offers superior cosmetic results in most cases.

When BCCs involve the medial canthal area, the lacrimal drainage system may need to be excised to completely eradicate the tumor. If the punctum or a canaliculus is excised, the drainage system can often be salvaged and/or reconstructed by placing a stent. If the distal lacrimal drainage system must be sacrificed to clear tumor margins, reconstruction of the lacrimal outflow system is not undertaken until it is established that the patient is tumor-free.

The incidence of orbital invasion with BCC is 2%–4% and occurs most commonly in cases that have been inadequately treated, in clinically neglected tumors, in morpheaform tumors, or in tumors with perineural spread. Orbital exenteration may be required in such cases. Retrospective studies show that the mortality rate from ocular adnexal BCC is 3%. The vast majority of patients who have died from BCC had disease that started in the canthal area, had undergone prior radiation therapy, or had clinically neglected tumors.

Histologic examination of the margins of an excised malignant tumor should confirm complete tumor removal. During surgery, frozen section techniques can be used in which the clinically apparent tumor, along with 1–2 mm margins, is excised, oriented on a detailed drawing, and sent to pathology for immediate frozen section evaluation.

Reconstruction is undertaken when all margins are found to be free of tumor. Some tumors have subcutaneous extensions that are not recognized preoperatively. Consequently, the surgeon must always be prepared to do a much larger reconstruction than originally anticipated from the clinical appearance of the tumor.

To facilitate complete removal of recurrent, infiltrative, morpheaform tumors and tumors in the medial canthus, dermatologists with special training in *Mohs micrographic surgery* can use this technique to remove thin layers of tumor via 3-dimensional mapping. This gives the highest success and clearance rates while minimizing defect size. Mohs surgery is indicated for any BCC on the eyelids and face and can also be used for squamous cell carcinoma. Preoperative planning involving both the micrographic surgeon and the oculoplastic surgeon enables the most efficient patient care. In some cases, micrographic excision may allow the globe to be retained, whereas conventional surgical techniques might indicate the need for exenteration. However, a limitation of Mohs micrographic surgery is in identifying the margins of the tumor if it has invaded orbital fat.

After Mohs tumor resection, the eyelid should be reconstructed by the ophthalmologist. (Reconstruction techniques are reviewed in Chapter 11.) Although urgent reconstruction is not critical, the procedure should be performed expeditiously. Early surgery affords maximum globe protection and fresh eyelid tissue margins for optimal reconstruction. If immediate reconstruction is not possible, the cornea should be protected by patching or temporarily suturing the remaining eyelid closed over the globe. If defects are small, spontaneous granulation may be a treatment alternative.

Radiation therapy should also be considered only as a palliative treatment and should generally be avoided for periorbital lesions. In particular, it should not be used for medial canthal lesions because of the risk of recurrence and orbital invasion. Histologic margins cannot be evaluated, and the recurrence rate is higher with radiation treatment compared with surgical treatment. Tumor recurrence after radiation is more difficult to detect because it occurs at a longer interval after initial treatment. Prior radiation makes surgical treatment more challenging because of the compromised blood supply and impaired healing. Adverse effects of radiation therapy in the periocular region include cicatricial changes of the skin/eyelids, scarring and obstruction of the lacrimal drainage system, keratoconjunctivitis sicca, and radiation-induced malignancy. Radiation may also cause cataract formation, retinopathy, or optic neuropathy. See also BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors*.

Oral vismodegib or sonidegib, hedgehog pathway inhibitors, may be useful treatments for metastatic or advanced orbital infiltrative BCC that is not amenable to surgical resection or radiation. Initial studies show that these drugs are effective, but long-term medication compliance can be challenging because of significant adverse effects, including muscle spasms, alopecia, change in taste, nausea, and diarrhea. Patients need to be carefully monitored for squamous cell carcinomas at uninvolved sites.

Cemiplimab and pembrolizumab, checkpoint inhibitors targeting the protein programmed cell death-1 (PD-1), have been approved for treating advanced BCC in patients whose disease has progressed, or who have had no response to, or were intolerant of prior hedgehog pathway inhibitor treatment.

Demirci H, Worden F, Nelson CC, Elner VM, Kahana A. Efficacy of vismodegib (Erivedge) for basal cell carcinoma involving the orbit and periocular area. *Ophthalmic Plast Reconstr Surg*. 2015;31(6):463–466.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) accounts for 20% of all cutaneous malignancies, but approximately 5%–10% of eyelid malignancies. Large longitudinal studies have shown that the age-adjusted incidence of SCC has increased by 200% in the past 3 decades. Although less common than BCC of the eyelid, SCC is clinically more aggressive (Fig 10-48). Tumors can arise spontaneously or from areas of solar injury and actinic keratosis and may be potentiated by immunodeficiency/immunosuppression. Cutaneous SCC is the most common malignancy to occur after a solid organ transplant.

Treatment for SCC is similar to that for BCC. Mohs micrographic resection or surgical excision with wide margins and frozen sections is preferred because of the potentially lethal nature of this tumor. SCC may metastasize through lymphatic transmission, bloodborne transmission, or direct extension, often along nerves (perineural spread). Recurrences should be treated with wide surgical resection, possibly including orbital exenteration or neck dissection, and may require collaboration with a head and neck cancer surgeon, medical oncologist, and radiation oncologist. Checkpoint inhibitor immunotherapies, specifically PD-1 inhibitors, have become a promising option for patients with advanced, recurrent, unresectable, or metastatic SCC of the head and neck.

Sebaceous carcinoma

Sebaceous carcinoma (also called sebaceous gland carcinoma, sebaceous cell carcinoma, sebaceous adenocarcinoma, or meibomian gland carcinoma) is a highly malignant and potentially lethal tumor that arises from the meibomian glands of the tarsal plate; from the glands of Zeis associated with the eyelashes; or from the sebaceous glands of the caruncle, eyebrow, or facial skin. Unlike basal cell or squamous cell carcinoma, sebaceous carcinoma occurs more frequently in women and originates twice as often in the upper eyelid as in the lower, reflecting the greater numbers of meibomian and glands of Zeis in the upper

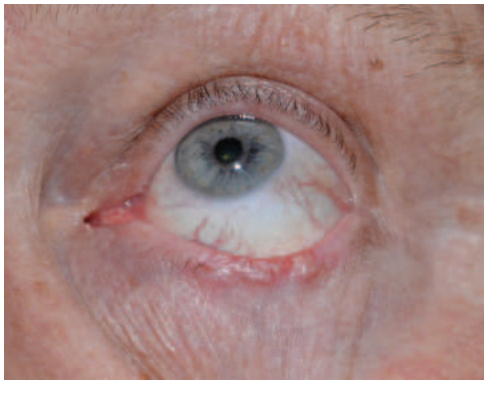

Figure 10-48 Squamous cell carcinoma of the left lower eyelid with diffuse madarosis. *(Courtesy of Bobby S. Korn, MD, PhD.)*

eyelid. Multicentric origin is common, and separate upper and lower eyelid tumors occur in 6%–8% of patients. Patients are commonly older than 50 years, although tumors have been reported in younger patients. It represents approximately 1% of periorbital malignancies in the United States.

These tumors typically appear yellow due to lipid material within the neoplastic cells and often masquerade as benign eyelid diseases. Clinically, they may simulate chalazia, chronic blepharitis, basal cell or squamous cell carcinoma, mucous membrane (ocular cicatricial) pemphigoid, superior limbic keratoconjunctivitis, or pannus associated with adult inclusion conjunctivitis. Typically, effacement of the meibomian gland orifices with destruction of hair follicles occurs, leading to madarosis (Fig 10-49).

In sebaceous carcinoma, the tumor within the tarsal plate tends to progress in an intraepithelial growth phase, which may extend over the palpebral and bulbar conjunctiva. A fine papillary elevation of the tarsal conjunctiva may indicate pagetoid spread of tumor cells; intraepithelial growth may replace corneal epithelium as well. Marked conjunctival inflammation and hyperemia may be present.

A nodule that initially simulates a chalazion but later causes eyelash loss and destruction of the meibomian gland orifices warrants biopsy because this presentation is characteristic of sebaceous carcinoma. Solid material from a chalazion that has been excised more than once should be submitted for histologic examination. Because histologic misdiagnosis can occur, the clinician should maintain suspicion based on clinical findings and request special stains (lipid) or additional histopathologic consultation if warranted. Any chronic unilateral blepharitis should raise suspicion of sebaceous carcinoma.

Muir-Torre syndrome (MTS) is an important consideration if a patient is diagnosed with sebaceous carcinoma. MTS is an autosomal dominant condition of sebaceous tumors (including sebaceous carcinoma, sebaceous adenoma, and basal cell epithelioma with sebaceous differentiation) involving the gastrointestinal, endometrial, or urologic systems.

Because eyelid margin sebaceous carcinomas originate in the tarsal plate or the eyelash margin, superficial shave biopsies may reveal chronic inflammation but miss the underlying tumor. Full-thickness eyelid biopsy with permanent sections or full-thickness

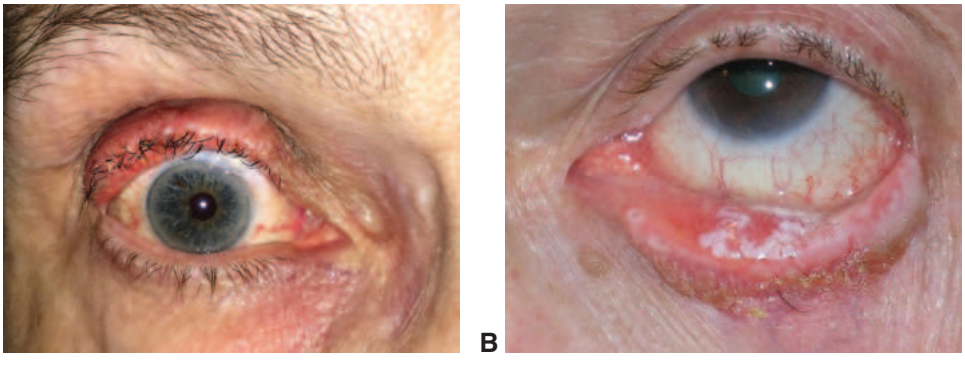

Figure 10-49 Sebaceous carcinoma. **A,** Right upper eyelid involvement causing diffuse thickening. **B,** Left lower eyelid pagetoid spread along the tarsal conjunctiva with diffuse madarosis. *(Courtesy of Cat N. Burkat, MD.)*

punch biopsy of the tarsal plate may be required to obtain the correct diagnosis. Characteristic histology findings of pale, foamy cytoplasm are covered in BCSC Section 4, *Ophthalmic Pathology and Intraocular Tumors.*

Management Wide surgical excision has historically been the standard treatment for sebaceous carcinoma, although Mohs micrographic surgery has been shown to result in lower local recurrence rates for periorbital sebaceous carcinoma. Overall, considerable caution is required because of pagetoid spread, skip lesions, and the polycentric nature of these tumors. Map biopsies of the conjunctiva are helpful to assess for pagetoid spread. If pagetoid spread is present, adjunctive cryotherapy or topical chemotherapy (mitomycin-C or 5-fluorouracil) may be used. Orbital exenteration (see Chapter 8 in this volume) may be considered for recurrent or large tumors invading through the orbital septum. These tumors usually metastasize to regional lymph nodes but may in rare cases spread hematogenously or through direct extension. Radiation therapy is not appropriate as a primary treatment modality, because sebaceous carcinomas are relatively radioresistant.

Evaluation of the lymph nodes begins with palpation for any lymphadenopathy on physical examination and possible diagnostic imaging to evaluate for enlarged or enhancing lymph nodes. Sentinel lymph node biopsy can be considered for patients with eyelid sebaceous cell carcinoma with high-risk features (recurrent lesions, or extensive involvement of the eyelid [>10 mm] or orbit), as well as for conjunctival or cutaneous melanoma with a Breslow thickness greater than 1 mm or Merkel cell carcinoma of the eyelid. Except for basal cell carcinoma, cancers of the eyelid and conjunctiva typically metastasize to the regional lymph nodes, and regional metastasis commonly occurs before metastasis to distant sites. Regional lymphadenectomy includes parotidectomy because of the lymphatic drainage routes of periorbital structures. Identification of regional nodal metastases may indicate that more extensive therapy is warranted, such as adjuvant radiation or chemotherapy, and can provide prognostic information to the physician and patient (Key Points 10-1).

Zhou C, Wu F, Chai P, et al. Mohs micrographic surgery for eyelid sebaceous carcinoma: a multicenter cohort of 360 patients. *J Am Acad Dermatol.* 2019 Jun;80(6):1608–1617.

KEY POINTS 10-1

Periorbital sebaceous carcinoma The following list highlights essential points for the ophthalmologist to remember about periorbital sebaceous carcinoma.

- Mohs micrographic surgery has been associated with lower local recurrence rates than wide local excision for periorbital lesions.
- Map biopsies of the conjunctiva should be performed to evaluate for skip lesions and pagetoid spread.
- Exenteration is considered for orbital invasion.
- Patients should be screened for Muir-Torre syndrome.
- Sentinel lymph node biopsy can be considered for sebaceous carcinomas greater than 10 mm in diameter.

- Regional lymphadenectomy and parotidectomy with adjuvant radiation are indicated for regional metastasis.
- Radiation therapy and chemotherapy are considered for recurrent or metastatic disease, not as a primary treatment modality.

Freitag SK, Aakalu VK, Tao JP, et al. Sentinel lymph node biopsy for eyelid and conjunctival malignancy: a report by the American Academy of Ophthalmology. *Ophthalmology*. 2020;127(12):1757–1765.

Melanoma

Although melanoma accounts for approximately 1%–2% of cutaneous cancers, it causes approximately 75% of deaths due to skin cancer. The incidence of melanoma in the United States has been steadily increasing during the past 30 years. Risk factors include sunlight exposure, tanning beds, genetic predisposition, and environmental mutagens. Cutaneous melanomas may develop de novo or from preexisting melanocytic nevi or lentigo maligna. Primary cutaneous melanoma of the eyelid skin is rare (<0.1% of eyelid malignancies). Melanoma should be suspected in any patient older than 20 years with an acquired pigmented lesion. Melanomas typically have variable pigmentation and irregular borders and may ulcerate and bleed.

There are 4 clinicopathologic forms of cutaneous melanoma:

- lentigo maligna melanoma
- nodular melanoma
- superficial spreading melanoma
- acrolentiginous melanoma

The eyelid is most often involved by either lentigo maligna melanoma or nodular melanoma. *Lentigo maligna melanoma* (Fig 10-50) represents the invasive vertical malignant growth phase that occurs in 2.0%–2.6% of patients with lentigo maligna. It accounts for 90% of head and neck melanomas. Clinically, the invasive areas are marked by nodule formation within the broader, flat, tan to brown irregular macule. The eyelid is usually involved by secondary extension from the malar region, and pigmentation may progress over the eyelid margin onto the conjunctival surface. Excision is recommended for a premalignant lentigo maligna and is mandatory in patients with lentigo maligna melanoma. Unlike the other

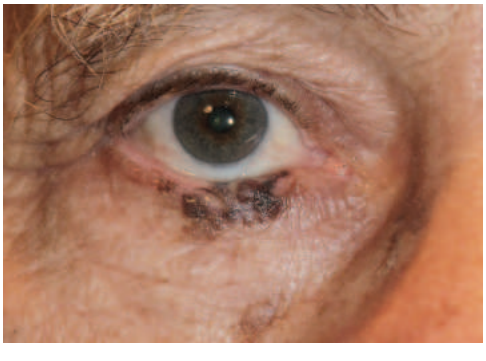

Figure 10-50 Lentigo maligna melanoma of the right lower eyelid. *(Courtesy of Bobby S. Korn, MD, PhD.)*

types of melanoma, lentigo maligna melanoma has a higher incidence of *p53* alterations compared with *BRAF* alterations. *Nodular melanoma* accounts for approximately 10% of cutaneous melanomas but is extremely rare on the eyelids (Fig 10-51). These tumors may be amelanotic. The vertical invasive growth phase is the initial presentation of these lesions; thus, they are likely to have extended deeply by the time of diagnosis.

Management Treatment of cutaneous melanoma includes wide surgical excision with histologic confirmation (using permanent sections) of complete tumor removal. Randomized trials have thus far provided insufficient information to determine optimal excision margins for primary cutaneous eyelid melanoma. In the periocular regions, margins less than 1 cm are often used to help preserve tissue needed for reconstruction and protection of the eye.

Regional lymph node dissection or sentinel lymph node biopsy may be performed for melanomas that have microscopic evidence of vascular or lymphatic involvement or Breslow thickness greater than 1 mm. Complete preoperative metastatic workup is indicated for tumors with thickness greater than 1.5 mm. Thin lesions (<0.75 mm) confer a 5-year survival rate of 98%, whereas thicker lesions (>4 mm) with ulceration have a survival rate of less than 50%. Because tumor thickness has strong prognostic implications, a punch biopsy that allows a core to be taken through the full tumor depth should be performed. Biopsy of these lesions does not increase the risk of metastatic spread.

Although cryotherapy may have a role in the treatment of acquired melanomas in the conjunctiva, it should not be considered for the treatment of cutaneous melanoma. Topical imiquimod cream can be considered in some cases of very early melanomas that are located in sensitive areas of the face where surgery may be disfiguring.

Immunotherapy can help stimulate the immune system or enhance the ability of immune cells to recognize and attack cancer cells. Because this modality can also affect healthy cells, side effects such as flulike symptoms, fatigue, skin rashes, and gastrointestinal problems may occur. Immunotherapy drugs can be used as a first-line treatment for melanoma or in combination with chemotherapy or surgery.

Cytokines, such as interleukin-2 and peginterferon alfa-2b, are US Food and Drug Administration (FDA)-approved adjuvant therapies for metastatic melanoma that has been surgically resected but has a high risk of recurrence. These agents help stimulate the rapid

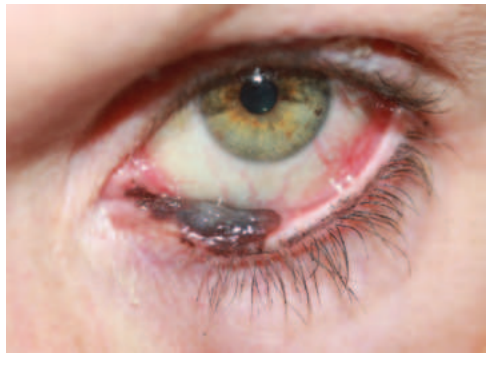

Figure 10-51 Malignant melanoma of the left lower eyelid that involves the eyelid margin, conjunctiva, and caruncle. *(Courtesy of Jill Foster, MD.)*

growth and activity of immune cells. However, recent randomized trials of interferon used in an adjuvant setting show that it can lengthen the time to melanoma recurrence but does not appear to prolong survival. These drugs may also be given in conjunction with chemotherapy for metastatic melanoma.

Checkpoint inhibitors block signaling proteins that would otherwise prevent activated T cells from attacking the tumor, thus allowing the immune system to induce tumor regression in cases of advanced or metastatic melanoma. Ipilimumab, which stimulates T cells, was the first drug of this type to be approved. It was followed by pembrolizumab and nivolumab, which target PD-1, a protein on T cells that normally helps keep T cells from attacking other cells in the body. By blocking PD-1, these drugs boost the immune response against melanoma cells, causing tumor regression. Nivolumab has been approved as a single agent for first-line therapy in inoperable or metastatic melanoma, or as a second-line treatment after treatment with ipilimumab. Some trials showed nivolumab improved survival in treated patients when compared with chemotherapy. Combination therapy using nivolumab and ipilimumab has demonstrated improved responses; however, the risk of adverse effects, such as elevated liver enzymes, gastrointestinal toxicities, and severe pneumonitis, increases. Nivolumab has recently received accelerated approval as a single agent in the treatment of melanoma with a *BRAF* V600 alteration.

Kaposi sarcoma

Kaposi sarcoma, which is associated with human herpesvirus 8, presents as a chronic reddish dermal mass (Fig 10-52) and is a frequent manifestation of HIV/AIDS, although it may also occur in senior or immunocompromised patients, such as those who have received organ transplants. Conjunctival lesions can be mistaken for a foreign-body granuloma or cavernous venous malformation. The lesion is composed of spindle cells of

Figure 10-52 Kaposi sarcoma of the right upper and left lower eyelids in a patient with HIV/AIDS. *(Courtesy of Reza Vagefi, MD.)*

Figure 10-53 Merkel cell carcinoma of the left upper eyelid. *(Courtesy of Cat N. Burkat, MD.)*

probable endothelial origin. It may be treated with cryotherapy, excision, radiation, or intralesional chemotherapeutic agents. If Kaposi sarcoma is related to AIDS, it may regress with adequate antiviral treatment of the underlying HIV infection.

Merkel cell carcinoma

The Merkel cell is part of the dendritic (neuroendocrine) cell population of the skin and plays a role in mediating the sense of touch. Merkel cells can give rise to malignant neoplasms, 10% of which occur in the eyelid and periocular area and manifest as painless, erythematous nodules with overlying telangiectasias (Fig 10-53). Merkel cell carcinoma can mimic other malignant lesions, making diagnosis difficult. One-third of the tumors recur after excision, and there is a high rate of metastasis. The estimated 5-year survival rate is 50%. Initial treatment should include aggressive wide surgical resection, with consideration of postoperative radiation and/or chemotherapy. Sentinel lymph node biopsy should be considered in guiding prognosis and adjuvant treatment.

Immunotherapy has become an important new therapy in treating advanced and metastatic Merkel cell carcinoma. Pembrolizumab, a PD-1 inhibitor, and avelumab, which blocks the PD-1 ligand, are both FDA approved to treat Merkel cell carcinoma and show more durable response rates compared with chemotherapy.

Nghiem P, Bhatia S, Lipson EJ, et al. Durable tumor regression and overall survival in patients with advanced Merkel cell carcinoma receiving pembrolizumab as first-line therapy. *J Clin Oncol*. 2019; 37(9):693–702.

CHAPTER 11

Reconstructive Eyelid Surgery

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- Precise anatomic tissue realignment during primary repair can prevent the need for secondary repair, which may require more extensive tissue rearrangement due to cicatrization.
- Reconstructive techniques that place incisions along the relaxed skin tension lines should be considered for a less visible scar.
- Postoperative interventions to modulate wound healing, contracture, and scarring, such as 5-fluorouracil injections, may be necessary to ensure long-term surgical success.
- Traumatic ptosis should be observed for several months to allow for possible spontaneous improvement before repair is considered.
- Horizontal eyelid tension is preferred over vertical tension during tissue closure to prevent postoperative eyelid retraction.

Eyelid Trauma

Eyelid injuries can be classified as blunt trauma or penetrating trauma. The following cardinal rules apply to the management of both types of eyelid trauma:

- Apply detailed knowledge of eyelid and orbital anatomy.
- Take a careful history.
- Record the best visual acuity for each eye.
- Thoroughly evaluate the globe and orbit.
- Obtain appropriate radiologic studies.
- Perform the best possible primary repair.

Blunt Trauma

Ecchymosis and edema are the most common presenting signs of blunt eyelid trauma. A thorough slit-lamp evaluation and dilated fundus examination should be performed to identify intraocular injury. Computed tomography may be indicated to assess for orbital fracture. See Chapter 6 for further discussion of orbital fractures.

Penetrating Trauma

Eyelid laceration treatment depends on the depth and location of the injury. Detailed knowledge of eyelid anatomy is required to optimize the initial repair and reduce the need for secondary repairs.

Lacerations not involving the eyelid margin

Superficial eyelid lacerations involving only the skin and orbicularis oculi muscle usually require only skin sutures, with or without buried subcutaneous sutures. Unnecessary scarring can be prevented by following the basic principles of repair, including conservative wound debridement, use of small-caliber sutures, wound-edge eversion, and early suture removal.

The presence of orbital fat in the wound indicates that the orbital septum has been violated (Fig 11-1). Prior to repair, any foreign bodies in the wound should be identified and removed, and the wound should be properly irrigated. Orbital fat prolapse in an upper eyelid wound is an indication for exploration of the levator muscle and aponeurosis. If the levator muscle or aponeurosis is lacerated, repair may be required to restore normal function. Upper eyelid retraction and tethering to the superior orbital rim are common when the orbital septum or levator is inadvertently incorporated into the repair. Orbital septum lacerations do not require repair; suturing the septum can lead to vertical shortening of the septum and result in eyelid retraction.

Lacerations involving the eyelid margin

When margin-involving eyelid lacerations are repaired, various techniques can be used to prevent notching of the margin (Figs 11-2, 11-3). Eyelid margin reapproximation is performed using interrupted or vertical mattress sutures to align the eyelash line, gray line, and mucocutaneous junction. These sutures are tied to cause slight eversion of the wound edges, allowing for wound contraction during healing. The nonmarginal cut edges of the tarsus are reapproximated in a lamellar fashion (ie, partial-thickness sutures through the tarsus) to strengthen wound closure and prevent tarsal edge imbrication and corneal abrasion. Suture tails are directed away from the ocular surface to prevent corneal irritation. Silk sutures can be used if the patient is amenable to postoperative suture removal in the clinic; otherwise, resorbable, buried vertical mattress sutures can be used.

Figure 11-1 Left upper eyelid laceration through the orbital septum with orbital fat prolapse. *(Courtesy of Cat N. Burkat, MD.)*

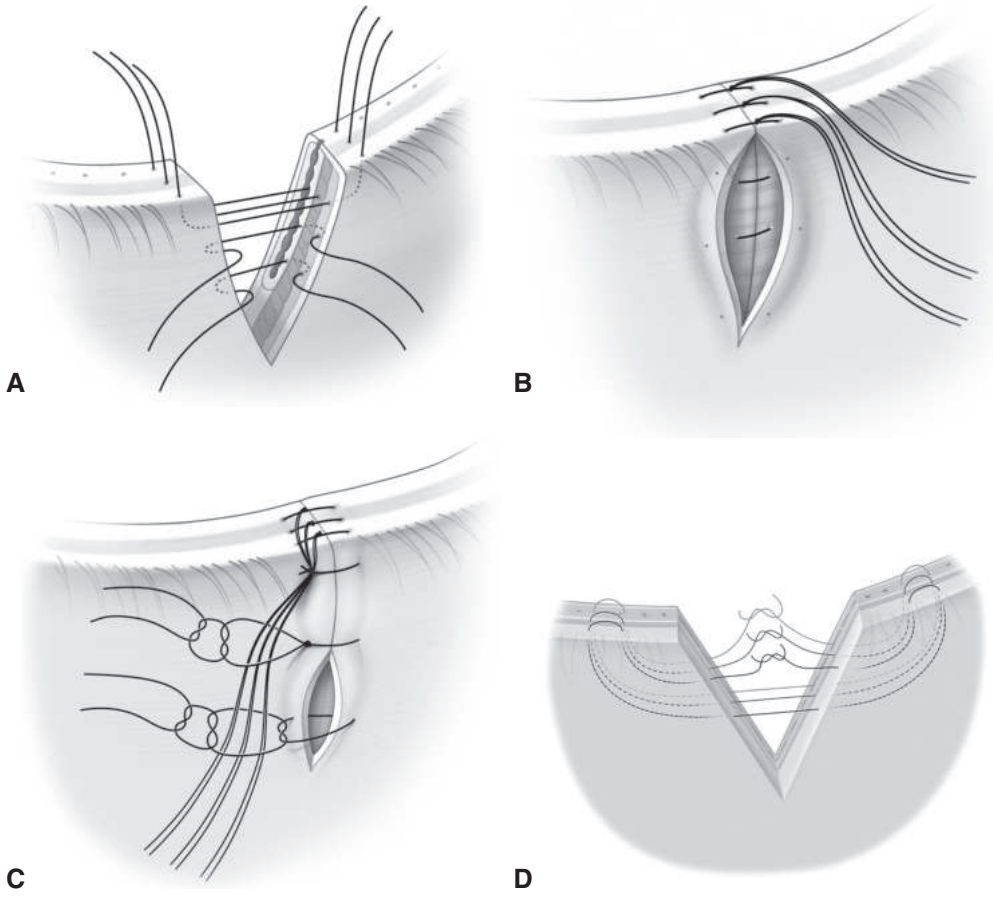

Figure 11-2 Eyelid margin repair. **A,** The eyelid margin is aligned with silk sutures through the eyelash line, gray line, and mucocutaneous junction (tarsus). The cut edges of the tarsus are aligned with partial-thickness resorbable sutures. **B,** The tarsal sutures are tied and cut; the eyelid margin sutures are tied and left long. **C,** The skin surface of the eyelid is sewn closed, and the skin sutures are used to tie down the tails of the margin sutures. **D,** An alternative approach is to place resorbable vertical mattress sutures in the eyelash line, gray line, and mucocutaneous junction, burying the knots away from the eyelid margin. *(Parts A–C illustrations by Christine Gralapp; part D illustration by Mark Miller.)*

Figure 11-3 Complex full-thickness eyelid margin laceration repair. **A,** Full-thickness eyelid laceration involving the upper and lower eyelid margins *(arrows).* **B,** Silk sutures are anchored away from the eyelid margin to avoid corneal irritation. **C,** Postoperative result at 3 months. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Trauma involving the canthal soft tissue

Trauma to the medial or lateral canthal areas usually results from horizontal traction on the eyelid, which causes avulsion at the eyelid's weakest points, the medial or lateral canthal tendon. The medial canthal area and lacrimal drainage apparatus should be carefully evaluated for injury, and suspected canalicular injury should be confirmed by inspection, gentle probing, and irrigation (Fig 11-4). Canalicular lacerations are discussed in detail in Chapter 15.

The integrity of the inferior and superior limbs of the medial and lateral canthal tendons can be assessed by grasping each eyelid with toothed forceps and tugging away from the injury while palpating the insertion of the tendon. Medial canthal tendon avulsion should be suspected when rounding of the medial canthal angle and acquired telecanthus are observed. The optimal treatment approach depends on the extent of medial canthal tendon avulsion. Attention to the posterior tendinous attachment to the posterior lacrimal crest is critical. If the upper or lower limb is avulsed but the posterior attachment of the tendon is intact, the avulsed limb may be sutured to its stump or the periosteum overlying the anterior lacrimal crest. If the entire tendon, including the posterior portion, is avulsed but there is no naso-orbital fracture, the avulsed tendon may be wired through small drill holes in the

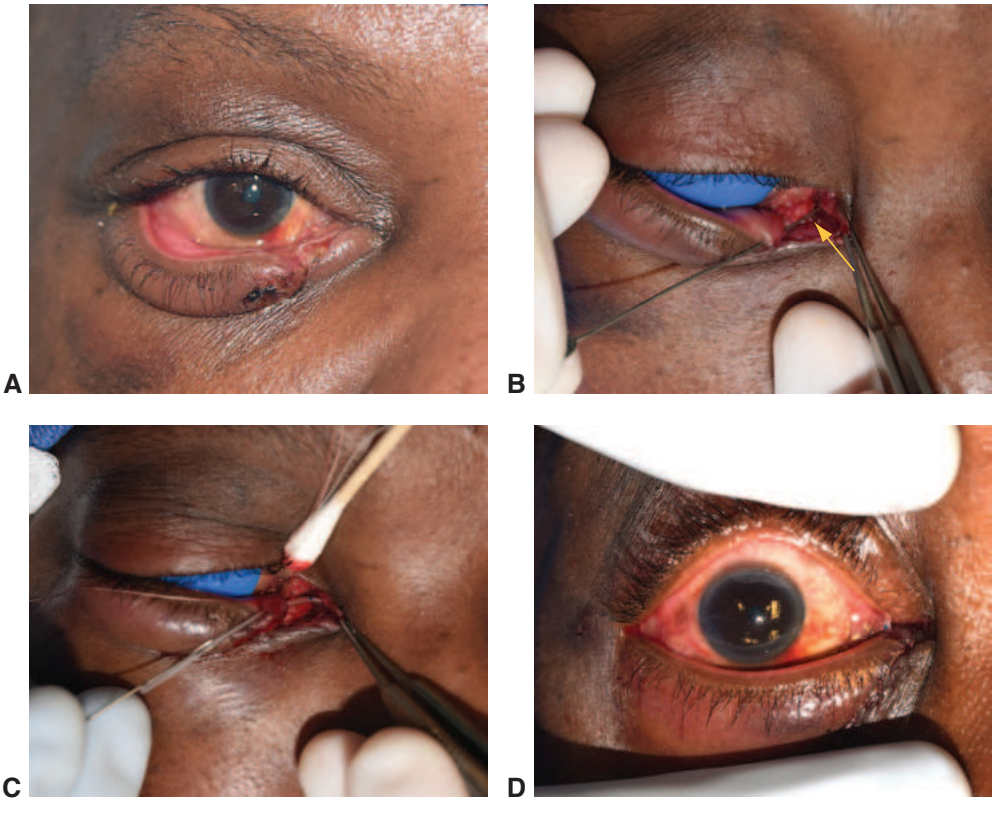

Figure 11-4 Repair of right lower eyelid laceration involving the canaliculus. **A,** Avulsion injury of the right lower eyelid. **B,** Lacrimal probe *(arrow)* placement demonstrating canalicular involvement. **C,** Lacrimal stent placement through the lacerated eyelid. **D,** Immediate postoperative result after reconstruction. *(Courtesy of Bobby S. Korn, MD, PhD.)*

ipsilateral posterior lacrimal crest. If the entire tendon is avulsed and there is a naso-orbital fracture, transnasal wiring or plating is necessary after fracture reduction. A T-shaped miniplate may be fixed anteriorly on the nasal bone, extending posteriorly into the orbit. The suture is sewn through the transected tendon and passed through holes in the miniplate. This technique is particularly helpful when the posterior lacrimal crest bone is absent.

Secondary Repair

Secondary repair following eyelid trauma usually involves treating cicatricial changes due to the original trauma or revising a suboptimal primary surgical repair that has lead to ectropion, entropion, eyelid retraction, or lagophthalmos (Fig 11-5). Scar revision may require a simple excision with primary closure or a more complex tissue rearrangement. The location of the scar in relation to the relaxed skin tension lines dictates the best technique, or combination of techniques, for scar revision. An elliptical scar excision is most useful for revising scars that follow the relaxed skin tension lines; single or multiple Z-plasty flap techniques can be used to revise scars that do not follow these lines.

Skin grafts, applied alone or in combination with various flaps, are used when tissue has been lost or when lengthening of the anterior lamella is required to correct scar contracture. Although any non–hair-bearing skin can be used for eyelid reconstruction, the ideal donor tissue is full-thickness upper eyelid skin that can be harvested as if performing a skin-only blepharoplasty. Alternate donor tissue include the pre- or post-auricular skin, supraclavicular skin, and upper inner arm skin. The ideal skin graft should be similar in color and thickness to the recipient-site skin with minimal actinic damage.

Tarsoconjunctival flaps or grafts are good substitutes for repairing posterior lamella eyelid defects when both the tarsal plate and conjunctiva are deficient. Buccal mucosa may be used when only the conjunctiva is missing. Hard palate composite grafts can be used for posterior lamella tarsal defects in the lower eyelid but should be avoided in the upper eyelid because the keratinized epithelium of the graft may irritate the cornea.

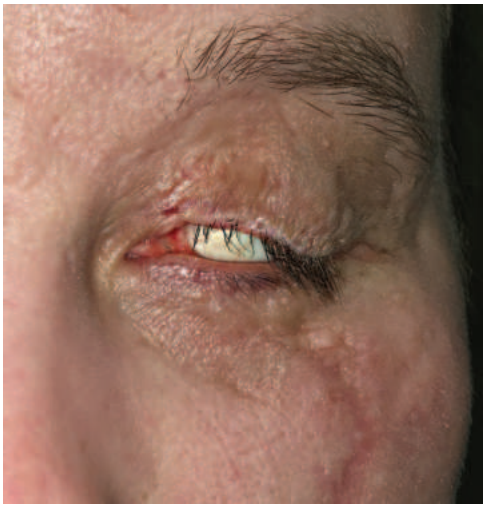

Figure 11-5 Anterior lamella cicatrix after trauma resulting in lagophthalmos. *(Courtesy of Cat N. Burkat, MD.)*

Surgical repair for traumatic ptosis should be delayed for 3–6 months after injury to allow for spontaneous improvement, except in cases of amblyogenic ptosis in young children.

Dog and Human Bites

Dog or human bites commonly result in tearing and crushing injuries, partial-thickness and full-thickness eyelid lacerations, canthal avulsions, and canalicular lacerations. Tissue loss is uncommon but may occur. Irrigation and early wound repair are preferred, and tetanus and rabies protocols should be observed. Systemic antibiotics are recommended for all bite wounds due to the high risk of infection, and amoxicillin-clavulanate is a good option for adults and children. Mixed organism flora specific to dog bites most often include *Pasteurella canis*, as well as aerobes (streptococci, staphylococci, *Moraxella, Neisseria*), and anaerobes *(Fusobacterium, Bacteroides, Porphyromonas*). Ocular, canalicular, and facial injuries are most commonly seen in children, often in association with dog bites from mixed breeds, German shepherds, Labrador retrievers, pit bull terriers, and rottweilers.

Prendes MA, Jian-Amadi A, Chang SH, Shaftel SS. Ocular trauma from dog bites: characterization, associations, and treatment patterns at a regional level I trauma center over 11 years. *Ophthalmic Plast Reconstr Surg.* 2016;32(4):279–283.

Burns

Isolated burns of the eyelid are rare; eyelid burns are generally seen in patients who have sustained extensive burns on the face and body. These patients are often semiconscious or heavily sedated and require ocular surface protection to prevent corneal exposure, ulceration, and infection. Early treatment involves the use of lubricating antibiotic ointments and moisture chambers and frequent evaluation of the globes and eyelids. If cicatricial changes begin in the periocular region and are not aggressively treated, relentless and rapid deterioration of the patient's ocular status often ensues due to cicatricial ectropion, lagophthalmos, and corneal exposure (Fig 11-6). If used, tarsorrhaphies should be more extensive than seems immediately necessary to mitigate the risks of cicatricial traction and dehiscence. In the past, skin grafting and reconstruction were often delayed for months after injury until cicatricial changes stabilized, which usually led to multiple surgeries and suboptimal outcomes. However, early and aggressive intervention after skin epithelialization can improve wound healing. Intralesional injections of wound-modulating agents (eg, 5-fluorouracil, triamcinolone) into the scar and fractional ablative laser resurfacing

Figure 11-6 Facial burns in the periocular region resulting in cicatricial brow elevation, upper eyelid ectropion, and lagophthalmos with exposure keratopathy. *(Courtesy of Bradford W. Lee, MD, MSc and Alexandra Levitt, MD, MPH.)*

can be very effective in treating and preventing cicatricial ectropion, contracture, and hypertrophic scarring. Laser treatment can also improve the texture and pigmentation of burn scars. When used appropriately, these interventions can provide an alternative or adjunct to delayed reconstructive surgery.

Lee BW, Levitt AE, Erickson BP, et al. Ablative fractional laser resurfacing with laser-assisted delivery of 5-fluorouracil for the treatment of cicatricial ectropion and periocular scarring. *Ophthalmic Plast Reconstr Surg.* 2018;34(3):274–279.

Eyelid and Canthal Reconstruction

Eyelid reconstruction may be needed to correct defects resulting from tumor resection as well as congenital and traumatic defects. Several techniques may be appropriate for the reconstruction of a particular eyelid defect; procedure selection depends on multiple factors, such as the patient's age and comorbidities, the condition of the eyelids, the size and position of the defect, and the surgeon's personal preference. Priorities in eyelid reconstruction are

- preserving eyelid function
- developing a stable eyelid margin
- ensuring adequate eyelid closure for ocular protection
- maintaining adequate vertical eyelid height
- creating a smooth, epithelialized internal surface
- maximizing cosmesis and symmetry

The following general principles guide the practice of eyelid reconstruction:

- Reconstruct either the anterior or posterior eyelid lamella with a graft, but not both; 1 of the layers must provide a blood supply *(pedicle flap)*.
- Direct tension horizontally and minimize vertical tension.
- Maintain sufficient and anatomical canthal fixation.
- Match tissue similar in color and thickness.
- Minimize the defect area as much as possible before sizing a graft.

Common sutures and needles used in eyelid reconstruction are listed in Table 11-1.

Eyelid Defects Not Involving the Margin

Defects not involving the eyelid margins can be repaired by direct closure if the repair does not distort the eyelid margin. The tension of closure should be directed horizontally because vertical tension may cause eyelid retraction or ectropion. Vertical tension may be avoided by the use of vertically oriented incisions.

If the defect is too large for direct closure, advancement or transposition of local flaps may be employed. The most commonly used flaps are advancement, rotational, and transposition flaps. Flaps usually provide the best tissue match and aesthetic result but require careful planning to minimize secondary deformities. The final texture, contour, and cosmesis are typically better with flaps than with skin grafts from sites other than eyelid skin.

If local flaps are not sufficient, eyelid defects can be repaired with full-thickness skin grafts from the upper eyelid. If this is not possible, grafts from the preauricular or

Table 11-1 Common Sutures and Needles Used in Oculoplastics

	Suture	Needle	Notes
Eyelid skin closure	6-0 express plain gut	PC-1	Dissolves over 2–4 weeks; can remove sooner to minimize scarring
	7-0 Vicryl suture	TG140-8	Dissolves over 1–2 months; can remove sooner to minimize scarring
	6-0 Prolene	P-1	Remove within 1–2 weeks
	6-0 nylon	P-1	Remove within 1–2 weeks
Brow, forehead, cheek closure	5-0 Prolene	P-3	Remove within 1–2 weeks
	5-0 fast-absorbing plain gut	PC-1	Remove within 1–2 weeks
Orbicularis closure	7-0 Vicryl suture	TG140-8	
Deep closures under tension	4-0 or 5-0 Monocryl	P-3	Good for subcuticular closure; minimal inflammation or granulomas
	4-0 or 5-0 Vicryl	P-3	Dissolves within 1–3 months; can cause suture granulomas
	4-0 or 5-0 Mersilene	S-2 or S-24	Permanent suture; can cause suture granulomas
Eyelid margin closure	6-0 silk	G-7	Remove within 1–2 weeks
Medial and lateral canthal closure	4-0 or 5-0 Vicryl	P-2 or P-3	Can cause suture granulomas
	4-0 or 5-0 Mersilene		Can cause suture granulomas
	4-0 or 5-0 Prolene	P-2, P-3, or PC-1	
Oral labial mucosa closure	4-0 chromic gut	S-2	

postauricular region, supraclavicular fossa, or inner upper arm may be used (Fig 11-7). However, grafts of greater thickness may limit upper eyelid mobility. Grafts should be slightly oversized because contraction is likely to occur.

Split-thickness grafts should be avoided in eyelid reconstruction. They are recommended only when adequate full-thickness skin is not available.

Eyelid Defects Involving the Eyelid Margin

Small upper eyelid defects

Small defects involving the upper eyelid margin can be repaired by primary closure if this technique does not place too much tension on the wound (Fig 11-8). Primary closure is usually employed when one-third or less of the eyelid margin is involved but may be possible for larger defects in cases of floppy eyelid syndrome or extensive eyelid laxity. If a larger area is involved, the advancement of adjacent tissue or grafting of distant tissue may be required. The superior limb of the lateral canthal tendon can be released to allow 3–5 mm of medial mobilization of the remaining lateral eyelid margin. Care must be taken to avoid the lacrimal ductules in the lateral upper eyelid during repair; ductule removal or destruction may lead to chronic dry eye. Postoperatively, the eyelid may initially appear tight and ptotic due to traction but typically relaxes over several weeks.

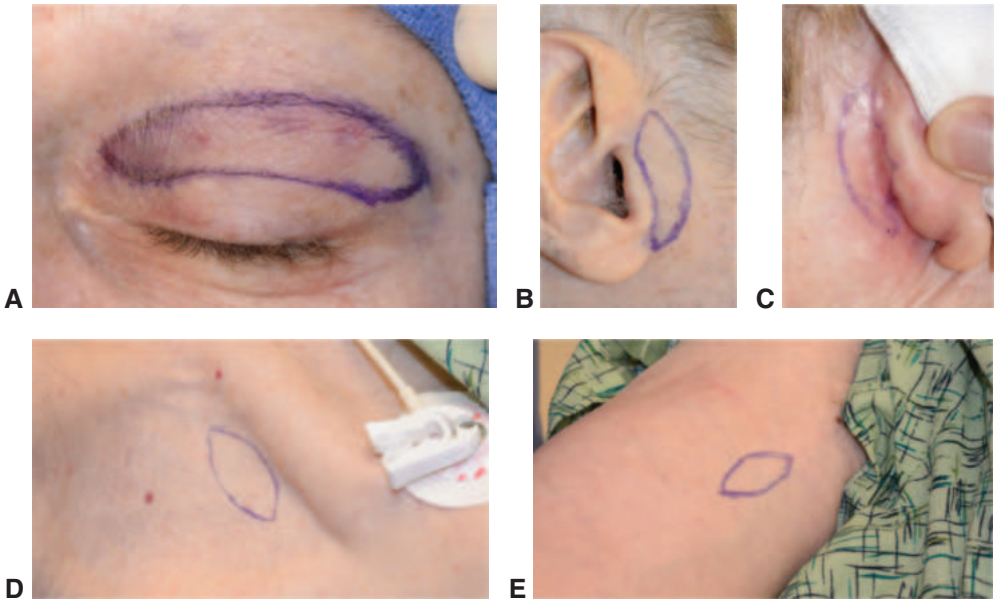

Figure 11-7 Possible donor sites for a full-thickness skin graft. **A,** Upper eyelid. **B,** Preauricular. **C,** Postauricular. **D,** Supraclavicular. **E,** Inner upper arm. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Moderate upper eyelid defects

Moderate upper eyelid margin defects (33%–50% margin involvement) can be repaired by advancing the lateral eyelid segment and temporal tissue. The lateral canthal tendon is released, and a semicircular skin flap is created below the lateral eyebrow, extending from the canthus to allow for further eyelid mobilization. The temporal branch of the facial nerve should be avoided when incising the flap. Tarsal-sharing procedures involving the lower eyelid may be required in younger patients with less eyelid laxity.

Large upper eyelid defects

Upper eyelid defects involving more than half of the upper eyelid margin often require eyelid-sharing techniques or tarsoconjunctival grafts. A Cutler-Beard flap (Fig 11-9) begins with a horizontal full-thickness blepharotomy incision 1–2 mm below the inferior border of the tarsus in the lower eyelid. The full-thickness lower eyelid flap is advanced into the defect of the upper eyelid behind the remaining lower eyelid margin. A second procedure is required to open the eyelids, and often results in a thick and relatively immobile upper eyelid. Alternatively, a tarsoconjunctival flap from the lower eyelid used in conjunction with an overlying skin graft may improve cosmesis. Eyelid-sharing procedures are less suitable for monocular patients or children in whom deprivation amblyopia may be a concern. A tarsoconjunctival graft taken from the contralateral upper eyelid and covered with a skin–muscle flap may be an option if adequate redundant upper eyelid skin is present.

Small lower eyelid defects

Small defects of the lower eyelid (involving less than one-third of the margin) can be repaired by primary closure (Fig 11-10). In addition, the inferior crus of the lateral canthal tendon can be internally or externally released to create an additional 3–5 mm of medial mobilization of the remaining lateral eyelid margin.

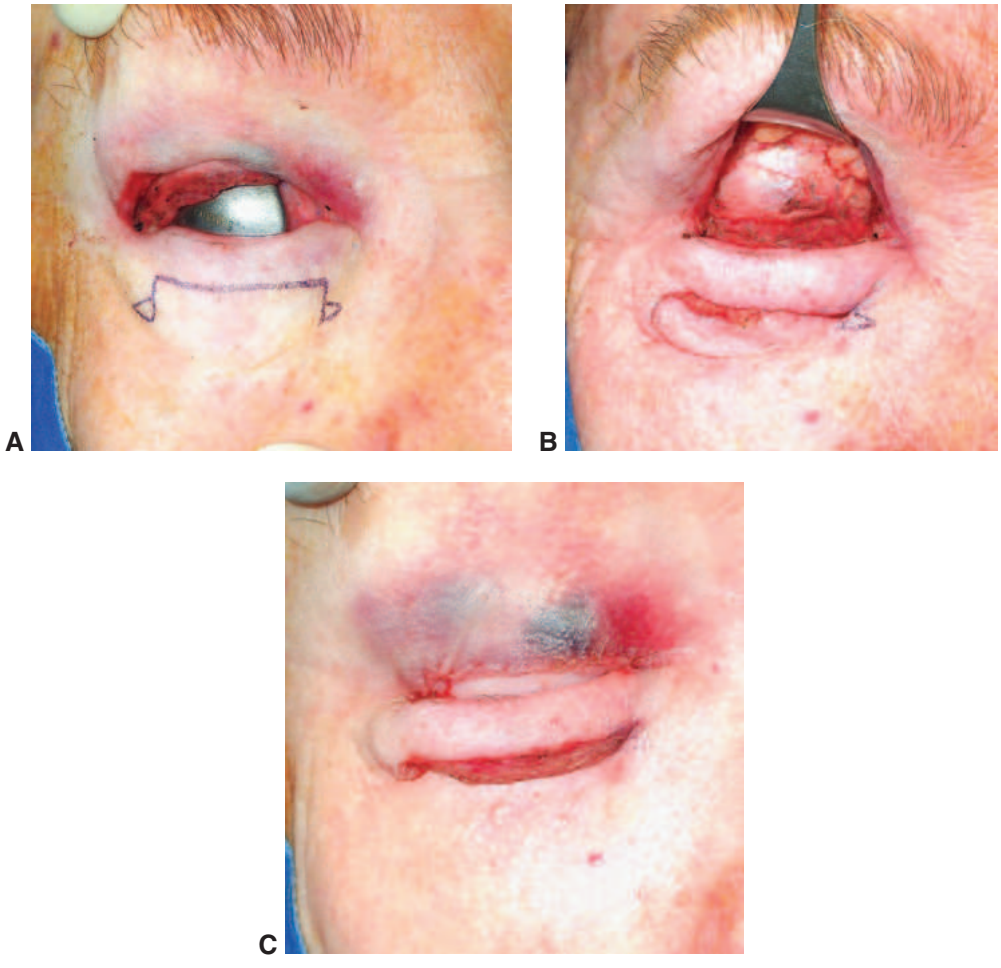

Figure 11-9 Upper eyelid reconstruction using lower eyelid skin and an orbicularis flap (Cutler-Beard flap). **A,** Extensive upper eyelid defect after basal cell carcinoma excision and planned blepharotomy incisions. **B,** Blepharotomy incision below the inferior border of the tarsus, creating a full-thickness lower eyelid flap. **C,** The flap is tunneled beneath the full-thickness lower eyelid bridge and inset into the upper eyelid recipient site. *(Courtesy of Steven M. Couch, MD.)*

Moderate lower eyelid defects

Semicircular rotational flaps, which were described earlier for upper eyelid repair, can also be used to repair moderate lower eyelid defects (involving approximately one-third to one half of the margin). Tarsoconjunctival autografts harvested from the underside of the upper eyelid may be transplanted into the lower eyelid defect to reconstruct the posterior lamella. When tarsal grafts are harvested, the marginal 4–5 mm height of the upper eyelid tarsus is preserved to prevent distortion of the donor eyelid margin. Tarsoconjunctival autografts may be covered with skin flaps or skin–muscle flaps. Cheek elevation (suborbicularis oculi fat lift) may be required to avoid ectropion and vertical traction on the eyelid. Alternatively, a tarsoconjunctival flap developed from the upper eyelid and

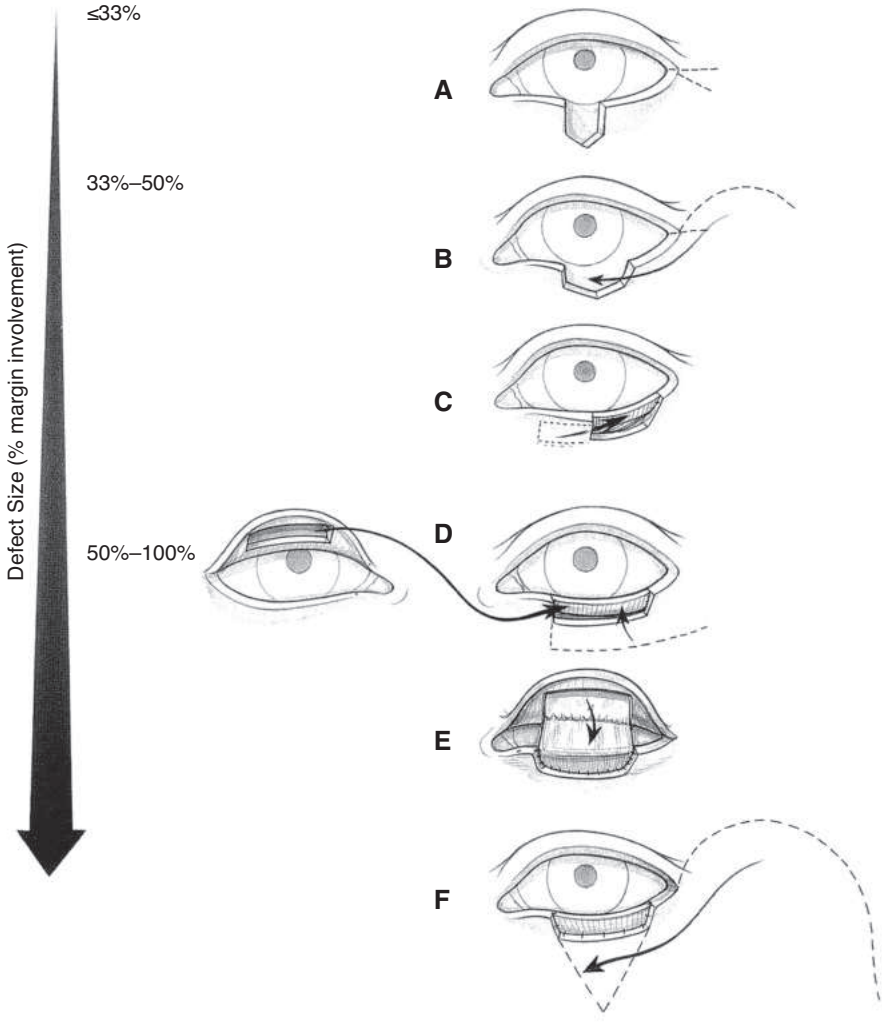

Figure 11-10 Reconstructive ladder for lower eyelid defects. **A,** Primary closure with or without lateral canthotomy or superior cantholysis. **B,** Semicircular flap. **C,** Adjacent tarsoconjunctival flap and full-thickness skin graft. **D,** Free tarsoconjunctival graft and skin flap. **E,** Tarsoconjunctival flap from upper eyelid and skin graft (modified Hughes flap). **F,** Composite graft with cheek advancement flap (Mustardé flap). *(Illustration by Christine Gralapp.)*

a full-thickness skin graft can be used (discussed in the next subsection) if the defect is on the larger side or if the case is not amenable to one of the other methods described.

Large lower eyelid defects

Defects involving more than half of the lower eyelid margin can be repaired using a tarsoconjunctival flap or graft in conjunction with an anterior lamellar flap or skin graft. A vertically based tarsoconjunctival flap (modified Hughes flap; Fig 11-11) from the upper

Lee, MD, MSc.)*

eyelid can be used with an anterior lamellar flap or skin graft to reconstruct a lower eyelid full-thickness defect. Like a tarsorrhaphy, this procedure occludes the eye for several weeks. The flap is divided and inset in a second procedure several weeks later after flap revascularization has occurred. An alternative to the vertically based tarsoconjunctival flap is the laterally based tarsoconjunctival flap, a single-stage procedure best suited for lateral defects of the lower eyelid, which has the advantage of not requiring eye occlusion (Fig 11-12).

Free tarsoconjunctival grafts from the upper eyelid covered with a vascularized skin flap can also be used to repair large defects. This reconstructive approach involves a single surgical stage and prevents temporary visual axis occlusion. If a free tarsoconjunctival graft is not possible, hard palate grafts, nasal septal chondromucosal grafts, and ear cartilage grafts can be used to reconstruct the posterior lamella.

Large rotating cheek flaps (Mustardé flap; Fig 11-13) can work well for large anterior lamellar defect repair and are used in conjunction with a posterior lamellar reconstructive

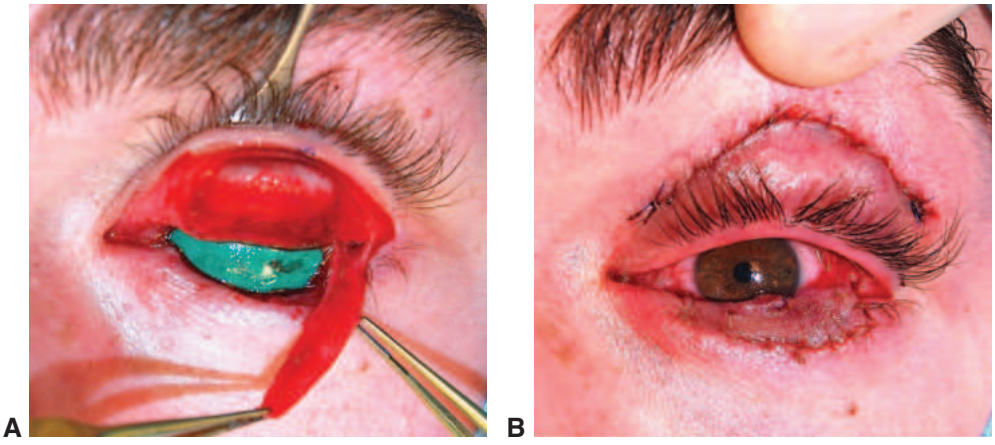

Fig 11-12 Reconstruction of a large full-thickness lower eyelid defect using a laterally based tarsoconjunctival flap and full-thickness skin graft. **A,** A tarsoconjunctival flap from the upper eyelid mobilized via a lateral pedicle. **B,** A full-thickness skin graft from the upper eyelid reconstructs the lower eyelid anterior lamella without visual axis occlusion. *(Courtesy of Don O. Kikkawa, MD.)*

option. Both the cheek rotation flap and the semicircular rotation flap may result in a rounded lateral canthus, which can be mitigated by creating a high arching incision toward the lateral end of the eyebrow emanating from the lateral commissure.

Hewes EH, Sullivan JH, Beard C. Lower eyelid reconstruction by tarsal transposition. *Am J Ophthalmol*. 1976;81(4):512–514.

Lateral Canthal Defects

Lateral canthal defects may or may not involve the lateral lower eyelid and can be repaired using a semicircular rotational flap (Tenzel flap, Fig 11-14), O-to-Z flap (Video 11-1), rhomboid flap (Fig 11-15), or laterally based upper eyelid pedicle flap (Fig 11-16). If the lower eyelid tarsus is involved, a horizontal strip of periosteum and/or deep temporal fascia left attached at the lateral orbital rim can be reflected medially and attached to the tarsal remnant to reconstruct the posterior lamella (see Fig 11-14). A Y-shaped periosteum pedicle flap can be used to reconstruct the entire lateral canthal posterior lamella of the upper and lower eyelids.

VIDEO 11-1 Lateral canthal defect repair using an O-to-Z flap.
Courtesy of Richard C. Allen, MD, PhD.

Medial Canthal Defects

Malignant lesions of the medial canthal region are excised with frozen sections and wide margins or Mohs micrographic surgery to minimize the risk of recurrence and invasion into the orbit and lacrimal drainage apparatus. If extensive sacrifice of both canaliculi is required when resecting a tumor, the patient may have to tolerate epiphora until tumor recurrence is deemed unlikely, after which a conjunctivodacryocystorhinostomy can be considered (see Chapter 15).

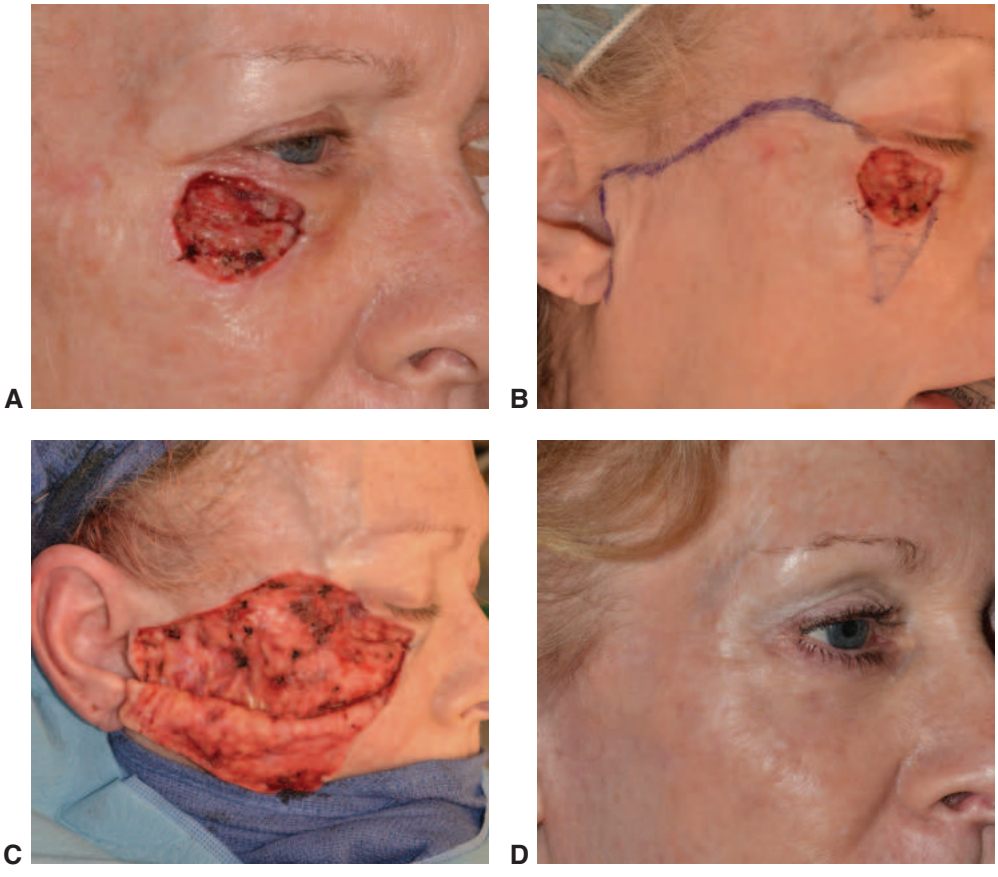

Figure 11-13 Reconstruction of a large right anterior lamellar defect using a rotational cheek flap (Mustardé flap). **A,** Defect after basal cell carcinoma excision. **B,** Skin marking for the rotational flap. **C,** Subcutaneous elevation of the flap showing the underlying superficial musculoaponeurotic system. **D,** Postoperative result 6 months after surgery. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Medial canthal defects are typically repaired using full-thickness skin grafts, glabellar flaps, or forehead flaps or allowed to heal by second intention. When full-thickness medial eyelid defects are present, medial canthal attachments should be fixed to the periosteum or bone with heavy permanent sutures (eg, Prolene, Mersilene), wire, or titanium miniplates. Defects involving the lacrimal drainage apparatus may require canalicular repair with lacrimal intubation.

Allowing medial canthal defects or other periocular defects to heal by second intention often results in acceptable functional and aesthetic outcomes. Patients must expect a longer healing time of up to 6 weeks for the defect to granulate and close. A second intention approach may be considered when surgical reconstruction is not practicable, there is insufficient donor tissue, or prior radiation has compromised the blood supply for reconstructive surgery. Hypertrophic scarring and cicatricial ectropion may occur in some cases, requiring surgical repair.

Lee, MD, MSc.)*

Full-thickness skin grafts are an excellent way to reconstruct medial canthal defects (Fig 11-17) and are thin enough to allow easy surveillance for tumor recurrence. However, full-thickness grafts are prone to postoperative contracture and may necessitate injections with wound-modulating agents. Skin grafts may not be desirable in some cases, such as when the defect involves the forehead or cheek and a skin graft would not restore adequate tissue depth. In these situations, an acellular dermal allograft or regeneration template may be considered.

The best aesthetic outcomes for medial canthal reconstruction are often achieved through careful forehead or glabellar flap transposition. However, these flaps can be thick, which may hinder the detection of recurrences. Forehead and glabellar flaps may require second-stage thinning or laser resurfacing to achieve the optimal cosmetic result.

The glabellar flap (Fig 11-18) is a triangular-shaped rotational flap with its base located between the brows and its apex pointing toward the forehead. Glabellar flaps are

rotated approximately 120 degrees to reconstruct medial canthal defects above the level of the canthus involving the side of the nose. The donor defects created by glabellar flaps are closed by sliding both brows toward the midline, resulting in a vertical incision and reduced distance between the brows.

The paramedian forehead flap (Fig 11-19) is a versatile flap that can be used to reconstruct medial canthal defects below the level of the canthus, involving the nose, cheek, or lower eyelid. The paramedian flap is a long axial flap with its base centered on its blood supply, the supratrochlear artery, approximately 1.7 cm from the midline. The exact course of the supratrochlear artery can be confirmed via Doppler ultrasonography. Paramedian forehead flaps are typically created contralaterally to the side of the medial canthal defect to reduce torsion at the pedicle base. The procedure requires two stages: the primary procedure and a division/inset procedure, which is performed after adequate vascularization has occurred.

CHAPTER 12

Periocular Malpositions and Involutional Changes

This chapter includes related videos. Go to www.aao.org/bcscvideo_section07 or scan the QR codes in the text to access this content.

Highlights

- Proper treatment of ectropion and entropion of the eyelids requires accurate identification of the underlying cause of the malposition.
- Important clinical measurements for evaluation of a patient with blepharoptosis include margin–reflex distance, vertical palpebral fissure height, upper eyelid crease position, levator function, orbicularis oculi muscle strength, and presence of lagophthalmos.
- Successful repair requires correct diagnosis, thorough understanding of facial anatomy, thoughtful planning, and good surgical technique.
- Chemical denervation with botulinum toxin is the mainstay of treatment for benign essential blepharospasm, with surgical myectomy considered in refractory cases.
- Treatment options for brow ptosis include internal browpexy, direct eyebrow elevation, endoscopic brow lift, and open brow-/forehead-lift.

History and Examination

Patients with eyelid malpositions require careful evaluation, including a history of the presenting condition and a general medical history. A detailed ocular examination, including visual acuity, pupillary examination, ocular and facial motility, slit-lamp examination, and testing of tearing and protective mechanisms should be performed. Accurate documentation of these findings with photographs is essential, and visual field testing is obtained as appropriate. For a general discussion of the perioperative management of ocular surgery, see BCSC Section 1, *Update on General Medicine.*

Ectropion

Ectropion (Fig 12-1) is an outward turning of the eyelid margin and may be classified as the following:

- congenital
- involutional
- cicatricial
- paralytic
- mechanical

Most cases seen in a general ophthalmology practice are involutional, with horizontal eyelid laxity being the primary cause. Horizontal lower eyelid tightening is the common component in surgical repair of the various types of ectropion (see the section "Horizontal eyelid tightening"). Congenital ectropion of the eyelid is rare and is discussed in Chapter 10 of this volume and in BCSC Section 6, *Pediatric Ophthalmology and Strabismus.*

Involutional Ectropion

Involutional ectropion results from horizontal eyelid laxity of the medial or lateral canthal tendons or both. Untreated, this condition leads to loss of eyelid apposition to the globe and eversion of the eyelid margin. Chronic conjunctival inflammation with hypertrophy and keratinization results from mechanical irritation and drying of the conjunctival surface. Involutional ectropion usually occurs in the lower eyelid because of the effects of gravity on a horizontally lax lower eyelid.

Horizontal eyelid tightening

The lower eyelid can be tightened by a variety of surgical procedures. Horizontal laxity can be detected by the *snapback test* or the *distraction test.* Lateral stretching of the eyelid at the time of the preoperative evaluation helps the surgeon assess whether lateral canthal resuspension would return the eyelid to its normal anatomic position (Fig 12-2A). In the *lateral tarsal strip procedure,* the tarsus is sutured directly to the lateral orbital rim periosteum (Fig 12-2B). The goal of this procedure is to correct the position of the eyelid while maintaining the horizontal dimension of the palpebral fissure and a sharp, correctly positioned lateral canthal angle (Video 12-1).

VIDEO 12-1 Medial spindle and lateral tarsal strip procedures.
Courtesy of Richard C. Allen, MD, PhD.

Laxity of the lower limb of the medial canthal tendon can be diagnosed by demonstration of excessive lateral movement of the lower punctum with lateral eyelid traction. Repair of medial canthal laxity is more challenging than repair of horizontal lower eyelid laxity, as the anterior and posterior limbs of the medial canthal tendon surround the lacrimal sac. The repair may be complicated by a kinking of the canaliculus or distraction of the punctum away from the globe, with resultant epiphora.

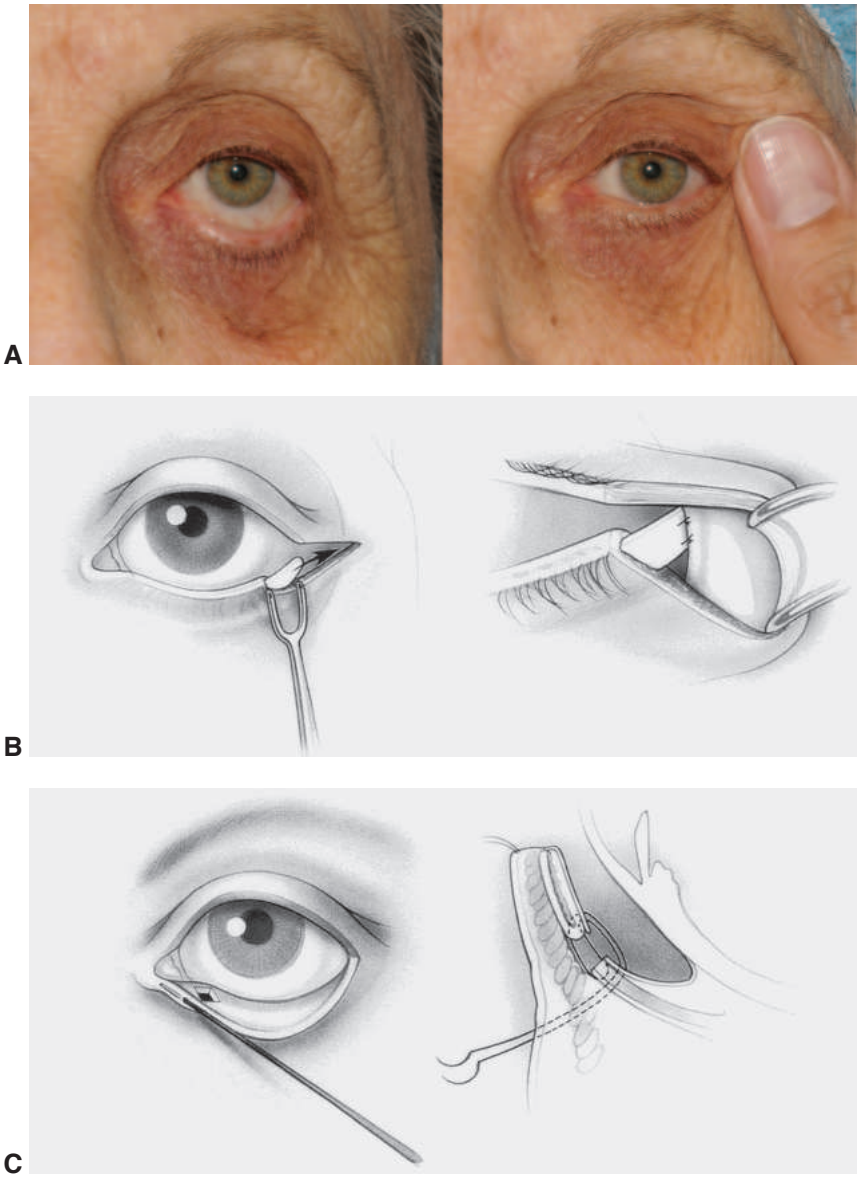

Figure 12-2 Lower eyelid tightening. **A,** Lateral stretching of the eyelid demonstrates the potential of lower eyelid tightening. **B,** Lateral tarsal strip procedure: anchoring the tarsal strip to periosteum inside the lateral orbital rim after shortening the eyelid. **C,** Medial spindle procedure: outline of excision of conjunctiva and retractors. *(Part A courtesy of Bobby S. Korn, MD, PhD; illustrations by Christine Gralapp.)*

Medial spindle procedure

In cases of mild medial ectropion with punctal eversion, a *medial spindle procedure* can be performed. The procedure involves a horizontal fusiform excision of conjunctiva and eyelid retractors 4 mm inferior to the punctum, followed by placement of inverting sutures

for closure (Fig 12-2C). In cases with associated horizontal eyelid laxity, lateral canthal tightening (see Fig 12-2B) may be used in conjunction with this procedure.

Repair of lower eyelid retractors

Retractor laxity, disinsertion, or dehiscence may be associated with ectropion, especially when the eyelid is completely everted, a condition known as *tarsal ectropion.* Attenuation or disinsertion of the inferior retractors may occur as an isolated defect or may accompany horizontal laxity in involutional ectropion. When both defects are present, retractor reinsertion is combined with horizontal tightening of the eyelid.

Paralytic Ectropion

See the section Facial Paralysis in this chapter.

Cicatricial Ectropion

Cicatricial ectropion of the upper or lower eyelid occurs when there is a deficiency of skin secondary to thermal or chemical burns, mechanical trauma, surgical trauma, or chronic actinic skin damage. Cicatricial ectropion can also be caused by chronic inflammation of the eyelid from dermatologic conditions such as rosacea, atopic dermatitis, or eczematoid dermatitis, or by scarring from herpes zoster infections. Furthermore, chronic blepharitis caused by progressive laxity can lead to cicatricial ectropion. Management consists of addressing the underlying cause, along with meticulous corneal lubrication. Cicatricial ectropion of the lower eyelid is usually treated in a 3-step procedure (Fig 12-3):

1. Vertical cicatricial traction is surgically released through an anterior approach.
2. The eyelid is horizontally tightened.
3. The anterior lamella is vertically augmented by means of a midface-lift, full-thickness skin graft, and/or adjacent tissue transfer, and the eyelid is temporarily placed on superior traction with a suture postoperatively.

Treatment of cicatricial ectropion or retraction of the upper eyelid usually requires only release of traction and augmentation of the vertically shortened anterior lamella with a full-thickness skin graft.

Although upper eyelid skin from the contralateral eye would be ideal for grafting, there is rarely enough tissue available from this source. The postauricular, preauricular, supraclavicular, and medial upper arm areas are other potential donor sites (see Chapter 11, Fig 11-7).

Mechanical Ectropion

Mechanical ectropion is usually caused by the gravitational effect of a bulky eyelid mass. Other causes include fluid accumulation, herniated orbital fat, or poorly fitted spectacles. Treatment is focused on addressing the underlying etiology.

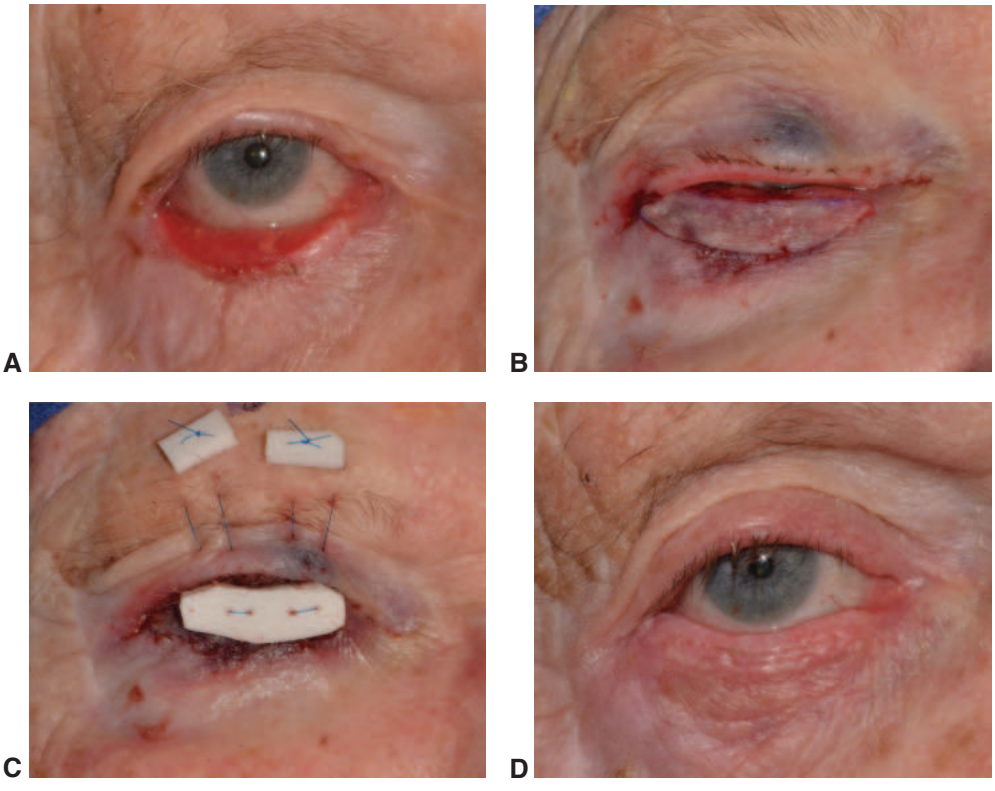

Figure 12-3 Repair of cicatricial ectropion. **A,** Preoperative appearance. **B,** Release of vertical cicatricial traction and placement of a full-thickness skin graft in association with lateral canthal tightening. **C,** Immobilization of the skin graft with a Frost suture. **D,** Final appearance after skin graft placement and lateral tarsal strip. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Entropion

Entropion is an inversion of the eyelid margin. Lower eyelid entropion (usually involutional) is much more common than upper eyelid entropion (usually cicatricial). Entropion may be unilateral or bilateral and is often classified as follows:

- congenital
- involutional
- acute spastic
- cicatricial

Congenital Entropion

Congenital entropion is discussed in Chapter 10.

Involutional Entropion

Involutional entropion most commonly occurs in the lower eyelids (Fig 12-4). Causative factors include horizontal laxity of the eyelid, attenuation or disinsertion of eyelid retractors,

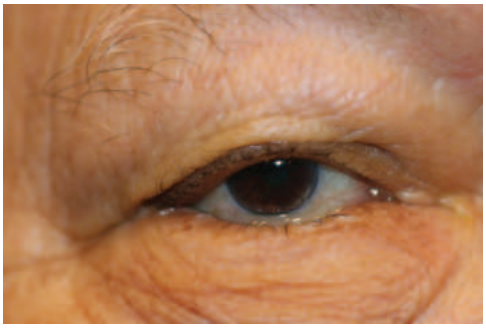

Figure 12-4 Involutional entropion of the right lower eyelid. *(Courtesy of N. Grace Lee, MD.)*

and overriding by the preseptal orbicularis oculi muscle. Horizontal laxity can be assessed with snapback and distraction testing. Such laxity is a result of senescence, which includes stretching of the eyelids and canthal tendons. Typically, the lower eyelid retractors maintain the eyelid margin in proper orientation. However, attenuation of the eyelid retractors (capsulopalpebral fascia and inferior tarsal muscle), in conjunction with preseptal orbicularis override, allows the inferior border of the tarsus to roll forward and superiorly, resulting in inward rotation of the margin. Several clinical clues may suggest disinsertion of the retractors:

- a white subconjunctival line several millimeters below the inferior tarsal border, caused by the leading edge of the detached retractors
- a deeper-than-normal inferior fornix
- elevation of the lower eyelid
- minimal movement of the lower eyelid on downgaze

After the entropic eyelid has been placed in its normal position, the clinician can detect superior override of the preseptal orbicularis by instructing the patient to forcefully close the eyelids. This maneuver accentuates the inward rotation of the lower eyelid margin. Procedures to repair involutional entropion of the lower eyelid fall into 3 groups: temporizing measures, horizontal tightening procedures, and retractor repair. Often, a combination of procedures is necessary. If trichiasis is present, it may require specific treatment, either in conjunction with the entropion repair or subsequently, if the eyelashes remain misdirected after proper positioning of the eyelid margin (see the Trichiasis section in this chapter).

Temporizing measures

Lubrication and a bandage contact lens may be used to protect the cornea from mechanical abrasion by the misdirected eyelashes. Rotational suture techniques (Fig 12-5) are occasionally helpful as temporizing measures in involutional entropion; however, when these techniques are used in isolation, recurrence is anticipated.

Surgical repair

Direct repair of lower eyelid retractor defects through a skin incision (Fig 12-6A) or a transconjunctival approach (Fig 12-6B) can be performed to stabilize the inferior border of the tarsus. In addition, a small amount of preseptal orbicularis oculi muscle can be removed in selected patients in whom it overrides the pretarsal orbicularis. Reinsertion of the eyelid retractors and limited myectomy of the orbicularis oculi in conjunction with a lower eyelid

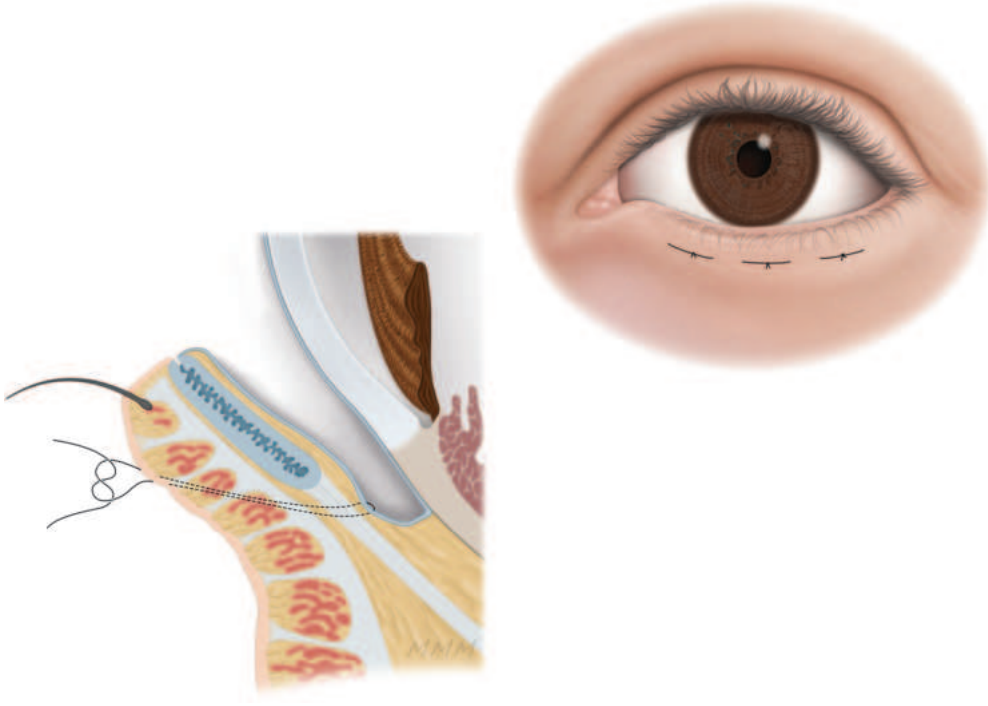

Figure 12-5 Rotational suture repair of spastic entropion. *(Illustration by Mark Miller.)*

tightening procedure, such as a lateral tarsal strip operation or wedge resection (see Fig 12-2B), correct all 3 etiologic factors in involutional entropion (Video 12-2).

VIDEO 12-2 Transconjunctival lower eyelid entropion repair.
Courtesy of Bobby S. Korn, MD, PhD.

Acute Spastic Entropion

Acute spastic entropion arises from ocular irritation or inflammation. Sustained contraction of the orbicularis oculi muscle leads to inward rotation of the eyelid margin. A cycle of increasing frequency of orbicularis muscle spasm caused by corneal irritation perpetuates the problem. The acute entropion usually resolves when the cycle is broken by treatment of the underlying cause.

Taping of the entropic eyelid to evert the margin or use of cautery or various rotational suture techniques (see Fig 12-5) afford temporary relief for most patients. In selected cases, botulinum toxin injection can be used to temporarily paralyze the overriding preseptal orbicularis muscle. However, involutional changes are often present in the eyelid; therefore, definitive surgical repair may be required.

Cicatricial Entropion

Cicatricial entropion is caused by vertical tarsoconjunctival contracture and internal rotation of the eyelid margin, with resulting irritation of the globe from inturned cilia

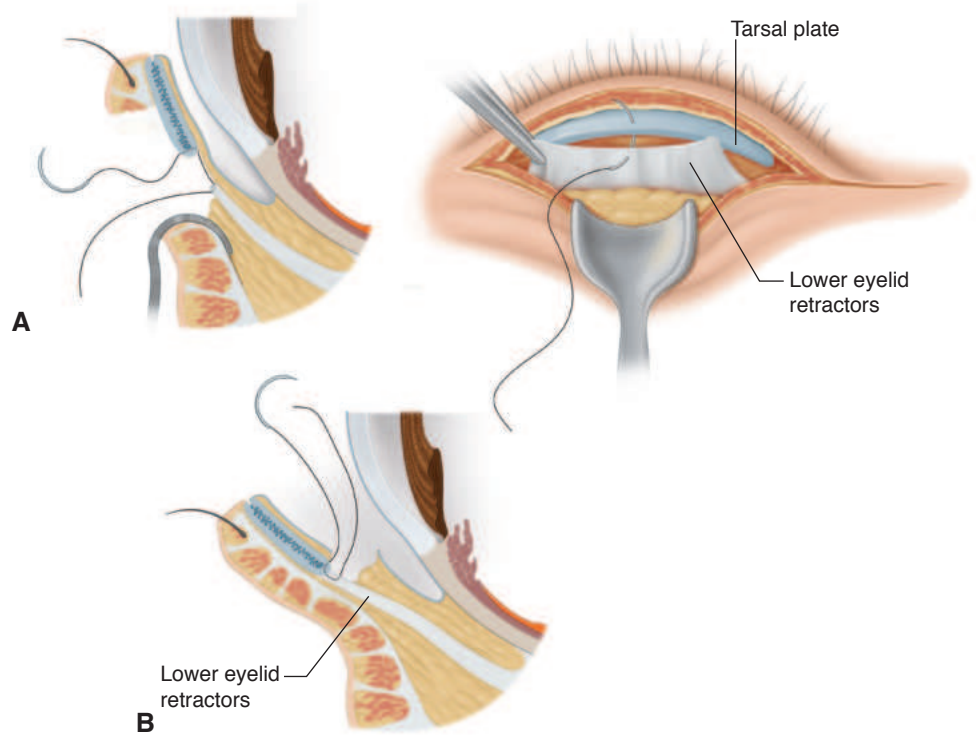

Figure 12-6 Retractor repair of lower eyelid involutional entropion. **A,** Transcutaneous approach. **B,** Transconjunctival approach. *(Illustration by Mark Miller.)*

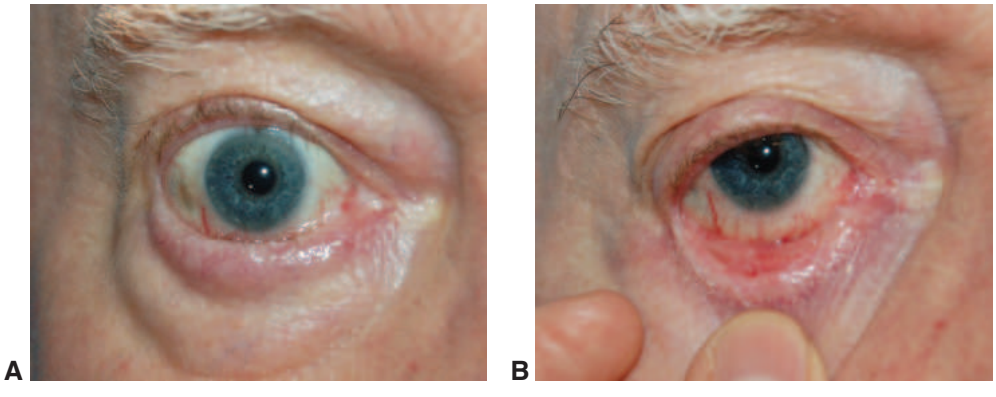

Figure 12-7 Cicatricial entropion. **A,** Entropion of the right lower eyelid. **B,** Eyelid everted, showing conjunctival scarring and shortening of the fornix. *(Courtesy of Don O. Kikkawa, MD.)*

or the keratinized eyelid margin (Fig 12-7). Various conditions may lead to cicatricial entropion, including *autoimmune* (mucous membrane [ocular cicatricial] pemphigoid), *inflammatory* (Stevens-Johnson syndrome, Fig 12-8), *infectious* (trachoma, herpes zoster), *surgical* (enucleation, posterior-approach ptosis correction, transconjunctival surgery), and *traumatic* (thermal or chemical burns, scarring) conditions. The long-term use of topical glaucoma medications, especially miotics and prostaglandin analogs, may

Figure 12-8 Stevens-Johnson syndrome with conjunctival scarring and eyelid margin keratinization. *(Courtesy of Bobby S. Korn, MD, PhD.)*

cause chronic conjunctivitis with vertical conjunctival shortening and secondary cicatricial entropion.

The patient's history, along with a simple diagnostic test *(digital eversion),* usually distinguishes cicatricial entropion from involutional entropion. Attempting to return the eyelid to a normal anatomic position using digital traction will correct the abnormal margin position in involutional entropion but not in cicatricial entropion. In addition, inspection of the posterior lamella may reveal scarring of the tarsal conjunctiva in cases of cicatricial entropion.

Management

Successful management of cicatricial entropion depends on careful preoperative evaluation to determine the cause, severity, and prominent features of the condition in each patient. When the etiology is autoimmune or inflammatory disease, the prognosis is guarded because of frequent disease progression.

Cicatricial entropion usually requires surgery, but lubricating eyedrops and ointments, barriers to symblepharon formation, and eyelash ablation with eyelash cautery are sometimes useful. Indeed, surgery is contraindicated, particularly on the conjunctival surface, during the acute phase of autoimmune diseases, and medical management of the inflammatory condition with topical and systemic medications is more appropriate until the disease stabilizes. When surgery is indicated, maximal inflammatory suppression is achieved with pulsed systemic anti-inflammatory medications (corticosteroids and immunosuppressive agents).

Tarsotomy (tarsal fracture) is useful in cases of mild to moderate cicatricial entropion *(marginal entropion)* of the upper or lower eyelid (Fig 12-9). In this situation, eyelashes abrade the cornea, and careful examination shows that the eyelid margin has lost its square edges and is rotated posteriorly. A posterior horizontal tarsal incision is made 2 mm distal to the eyelid margin; this incision through the full thickness of the tarsus allows the eyelid margin to be rotated away from the globe. The eyelid position is stabilized with everting sutures.

For margin rotation to be effective, the tarsus should be intact and of reasonably good quality. In patients with severe cicatricial entropion, the involved tarsus is usually scarred

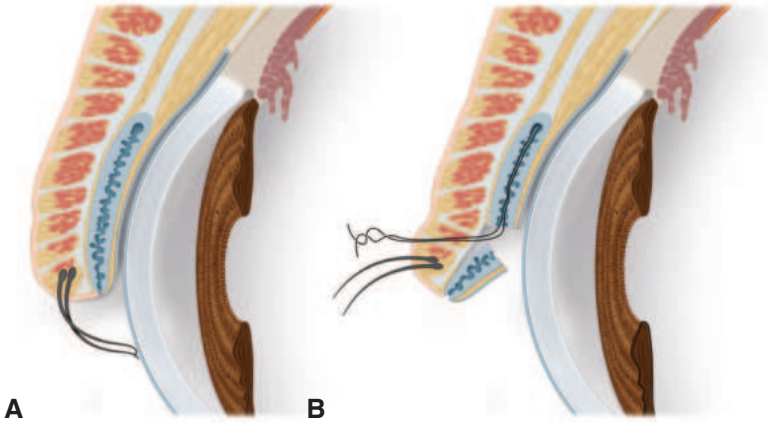

Figure 12-9 Tarsotomy. **A,** Cicatricial entropion with trichiasis. **B,** Tarsotomy with margin rotation. *(Illustration by Mark Miller.)*

and distorted and needs to be replaced. In the upper eyelid, tarsoconjunctival and other mucosal grafts are useful tarsal substitutes; in the lower eyelid, autogenous ear cartilage, preserved scleral grafts, hard-palate mucosa, and acellular dermal matrix (human and porcine) grafts have been used.

Symblepharon

Symblepharon is an adhesion between conjunctival surfaces. It can occur as a result of inflammation, infection, trauma, or previous surgery. Conjunctival Z-plasties are sometimes effective for localized contracted linear adhesions when vertical lengthening of the involved tissue is the primary objective. More extensive symblepharon formation requires a full-thickness conjunctival graft or flap, a partial-thickness mucous membrane graft, or an amniotic membrane graft.

Trichiasis

Trichiasis is an acquired misdirection of eyelashes (Fig 12-10). The treatment method is usually determined by the pattern (segmental or diffuse) of the misdirected eyelashes and the quality of the posterior lamella of the involved eyelid. Inturned eyelashes not associated with involutional entropion are usually seen in cases of chronic eyelid inflammation and posterior lamellar scarring *(marginal cicatricial entropion).* If the eyelid margin is misdirected, treatment should focus on correcting the entropion.

Management

Trichiasis may be initially treated with *mechanical epilation.* Because of eyelash regrowth, recurrence can be expected 3–8 weeks after epilation. Broken cilia are often more irritating

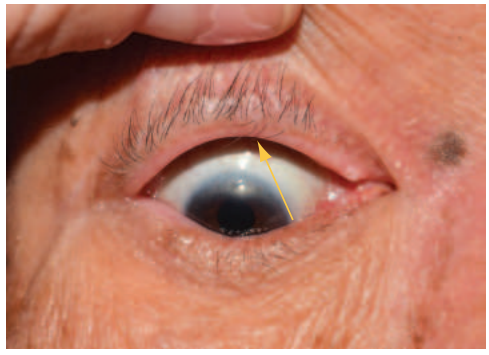

Figure 12-10 Trichiasis without entropion of the right upper eyelid *(arrow).* *(Courtesy of Bobby S. Korn, MD, PhD.)*

to the cornea than longer, mature eyelashes. The following treatments have been associated with longer therapeutic windows:

- *Electrolysis* or *radiofrequency ablation*. Energy is delivered through an insulated needle to destroy the hair follicle. When the needle tip is removed, the eyelash is easily extracted. Recurrence rate is high, adjacent normal eyelashes may be damaged, and scarring of the adjacent eyelid margin tissue can worsen the problem.
- *Cryotherapy*. The involved area is frozen for approximately 25 seconds, allowed to thaw, and then refrozen for 20 seconds *(double freeze–thaw technique).* The eyelashes are mechanically removed with forceps after treatment. Edema lasting several days, loss of skin pigmentation, notching of the eyelid margin, and possible interference with goblet cell function are disadvantages of cryotherapy.
- *Argon laser therapy.* Laser energy is delivered to the follicle; some pigment is required in the base of the lash to absorb the laser energy and ablate the lash, making this technique sensitive to hair color.

In all of these procedures, success rates vary, and additional treatment sessions are commonly necessary. An ophthalmic microtrephine can also be used to extract individual misdirected eyelashes. *Full-thickness pentagonal resection* with primary closure may be considered when trichiasis is confined to a limited segment of the eyelid.

Blepharoptosis

Blepharoptosis, also referred to as *ptosis,* is the inferior displacement of the upper eyelid. It is a common cause of reversible peripheral vision loss. Although the superior visual field is most often involved, central vision can also be affected. Many patients with ptosis report difficulty with reading because the ptosis worsens in downgaze. Ptosis has also been shown to decrease the overall amount of light that reaches the macula and, therefore, can reduce visual acuity, especially at night.

Upper eyelid ptosis can be classified by onset as *congenital* or *acquired.* It can be further categorized by the cause: *myogenic, aponeurotic, neurogenic, mechanical,* or *traumatic.* The most common type of congenital ptosis is myogenic and results from

a poorly developed levator palpebrae superioris muscle; the most common type of acquired ptosis is aponeurotic and is caused by stretching or disinsertion of the levator aponeurosis.

Evaluation

Many elements are involved in the evaluation of blepharoptosis. The history can provide pertinent clues, such as variability in the degree of ptosis, which suggests myasthenia gravis. Historical data can also be assessed by examining old photos or a driver license photograph. Affected family members may highlight potential heritable conditions such as oculopharyngeal or myotonic dystrophy. The physical examination further elucidates etiology through eyelid measurements, assessment of surrounding orbital and facial structures, and observation of head positioning and possible synkinetic movements. The pupils and tear film are also assessed. Further ancillary testing may be guided by additional history and clinical examination findings.

Eyelid measurements

Physical examination of the ptosis patient begins with 5 clinical measurements (Fig 12-11, Video 12-3):

- margin–reflex distances 1 and 2
- palpebral fissure height
- upper eyelid crease position
- levator function (upper eyelid excursion)
- presence of lagophthalmos

Margin–reflex distance 1	+0.5	+3.5
Margin–reflex distance 2	+5.5	+5.5
Palpebral fissure height	6.0	9.0
Upper eyelid crease	12	8
Levator function	15	15
Lagophthalmos	0	0

Figure 12-11 Evaluation of ptosis. Patient appearance and example of a ptosis data collection sheet. *(Courtesy of Bobby S. Korn, MD, PhD.)*

VIDEO 12-3 Eyelid measurements.
Courtesy of Richard C. Allen, MD, PhD.

The *margin–reflex distance 1 (MRD_1),* which is the distance from the upper eyelid margin to the corneal light reflex in primary position, is the single most important measurement in describing the amount of ptosis. In severe ptosis, the light reflex may be obstructed by the eyelid, and the MRD_1 has a zero or negative value. The more ptotic eyelid should be elevated to unmask occult contralateral ptosis, according to Hering's law of equal innervation (Fig 12-12). If the patient reports visual obstruction while reading, the eyelid position in downgaze is checked. Lower eyelid retraction (or scleral show) should be noted separately as the *margin–reflex distance 2 (MRD_2).* The MRD_2 is the distance from the corneal light reflex to the lower eyelid margin. The sum of the MRD_1 and the MRD_2 should equal the vertical palpebral fissure/palpebral fissure height.

The *vertical palpebral fissure* is measured at the widest point between the lower eyelid and the upper eyelid. This measurement is taken with the patient fixating on a distant object in primary gaze.

The distance from the *upper eyelid crease* to the eyelid margin is also measured. The insertion of fibers from the levator muscle into the skin contributes to formation of the upper eyelid crease; therefore, the crease is often elevated in patients with involutional ptosis and is often shallow or absent in patients with congenital ptosis. There is ethnic variation in baseline eyelid crease height, with the upper eyelid crease being typically lower or obscured in the Asian eyelid compared to the non-Asian eyelid.

Levator function is estimated by measuring the *upper eyelid excursion* from downgaze to upgaze. Fixating the brow with digital pressure minimizes contributions from accessory elevators of the eyelids, such as the frontalis muscle. Failure to negate the influence of the frontalis muscle results in overestimation of levator function, which may affect the diagnosis and treatment plan.

Finally, the patient should be assessed for *lagophthalmos;* if it is present, measurement of the gap between the eyelids should be noted (in millimeters). Lagophthalmos, poor orbicularis strength, and poor tear film quantity or quality may predispose the patient to complications of ptosis repair such as dryness and exposure keratopathy.

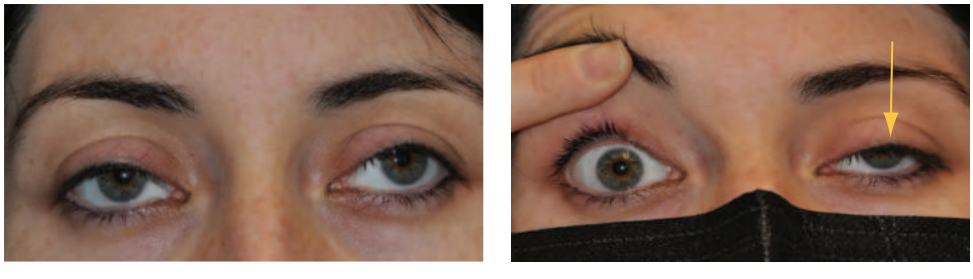

Figure 12-12 Unmasking of left upper eyelid ptosis *(arrow)* with elevation of ptotic left upper eyelid, demonstrating the effect of Hering's law of equal innervation in a patient who also has exotropia from myasthenia gravis. *(Courtesy of Lilangi Ediriwickrema, MD.)*

Additional assessments

Physical examination also includes checking *head position, chin elevation, brow position,* and *brow action* in attempted upgaze. These features help to show the patient how ptosis affects function. Quantity and quality of the tear film is documented in the initial examination. The examiner should also note the presence or absence of supraduction of the globe with eyelid closure *(Bell phenomenon)* and assess corneal sensation; these factors may affect the treatment plan.

Variation in the amount of ptosis with extraocular muscle or jaw muscle movements *(synkinesis)* occurs in several conditions, including Marcus Gunn jaw-winking ptosis, aberrant regeneration of the oculomotor nerve or the facial nerve, and some types of Duane retraction syndrome. The examiner should attempt to elicit synkinesis as part of the evaluation of patients with congenital blepharoptosis or those with possible aberrant regeneration.

The *position of the ptotic eyelid in downgaze* (palpebral fissure in downgaze) can help differentiate between congenital and acquired causes. The congenitally ptotic eyelid is typically higher in downgaze than the contralateral eyelid. The congenitally ptotic eyelid may also manifest lagophthalmos. By contrast, in acquired involutional ptosis, the affected eyelid remains ptotic in all positions of gaze and may even worsen in downgaze with relaxation of the frontalis muscle.

The ophthalmologist must assess *visual function* and *refractive error* in all cases of congenital or childhood ptosis in order to identify and treat the child with concomitant amblyopia that results from anisometropia, high astigmatism, strabismus, or occlusion of the pupil. Amblyopia occurs in approximately 20% of patients with congenital ptosis, thus, concomitant evaluation by a pediatric ophthalmologist may be necessary. *Extraocular muscle function* should also be assessed to identify potential congenital (combined superior rectus/levator muscle maldevelopment, congenital oculomotor palsy) and acquired (ocular or systemic myasthenia gravis, mitochondrial myopathy, oculopharyngeal dystrophy, oculomotor palsy with or without aberrant regeneration) conditions.

In addition, *pupillary examination* is important in the evaluation of ptosis. Pupil abnormalities are present in some acquired and congenital conditions associated with ptosis (eg, Horner syndrome, cranial nerve III palsy). Miosis that is most apparent in dim illumination is a finding in Horner syndrome; mydriasis is seen in some cases of oculomotor nerve palsy.

External examination may reveal other abnormalities as well. For example, severe bilateral congenital ptosis may be associated with telecanthus, epicanthus inversus, hypoplasia of the superior orbital rims, horizontal shortening of the eyelids, ear deformities, hypertelorism, and hypoplasia of the nasal bridge. These findings are classically seen in *blepharophimosis–ptosis–epicanthus inversus syndrome* (*BPES;* discussed in Chapter 10).

Ancillary testing

Visual field testing may be used to quantitate the patient's level of functional visual impairment. Comparison of visual fields with the eyelids elevated with tape to those with the eyelids in their natural ptotic state gives an estimate of the superior visual field improvement that can be anticipated following surgery. Visual field testing and external full-face photography may be required by third-party payers for insurance coverage.

Pharmacologic testing, pupillary evaluation in light and dark, and *lower eyelid elevation (smaller MRD_2)* may be helpful in confirming the clinical diagnosis of *Horner syndrome* and in localizing the causative lesion (see BCSC Section 5, *Neuro-Ophthalmology*). Third-order neuron dysfunction resulting in Horner syndrome is typically benign. However, neuron dysfunction of the first or second order is sometimes associated with malignant neoplasms such as an apical lung (Pancoast) tumor, aneurysm, or dissection of the carotid artery.

Pharmacologic testing may also be used in the diagnosis of myasthenia gravis (MG), a disease in which ptosis is the most common presenting sign. Fluctuating ptosis that seems to worsen with fatigue or prolonged upgaze—especially when accompanied by diplopia or other clinical signs of systemic MG such as dysphonia, dyspnea, dysphagia, or proximal muscle weakness—is an indication for further diagnostic evaluation with the edrophonium chloride, ice-pack, or acetylcholine receptor antibody tests. (Also see the section "Myasthenia gravis" in this chapter.)

Classification

Myogenic ptosis

The patient's history usually distinguishes congenital from acquired ptosis. *Congenital myogenic ptosis* results from dysgenesis of the levator muscle. Instead of normal muscle fibers, fibrous or adipose tissue is present in the muscle belly, diminishing the ability of the levator to contract and relax. Therefore, most congenital ptosis caused by maldevelopment of the levator muscle is characterized by decreased levator function, lid lag, and, sometimes, lagophthalmos (Fig 12-13). The upper eyelid crease is often absent or poorly formed, especially in patients with more severe ptosis. Congenital myogenic ptosis associated with a poor palpebral oculogyric reflex (Bell phenomenon) or with vertical strabismus may indicate concomitant maldevelopment of the superior rectus and levator muscles (*monocular elevation deficiency,* formerly called *double-elevator palsy*).

Acquired myogenic ptosis results from localized or diffuse muscular disease such as muscular dystrophy, mitochondrial myopathy (ie, chronic progressive external ophthalmoplegia), MG, or oculopharyngeal muscular dystrophy (Fig 12-14A). Because of the underlying muscle dysfunction, surgical correction may require a frontalis suspension or advancement procedure (Fig 12-14B).

Aponeurotic ptosis

The levator aponeurosis transmits levator palpebrae superioris muscle force to the eyelid. Thus, any disruption in its anatomy or function can lead to ptosis.

Acquired aponeurotic ptosis is the most common form of ptosis. It results from stretching or dehiscence of the levator aponeurosis or disinsertion from its normal position. Common causes are involutional attenuation or repetitive traction on the eyelid, which may occur with frequent eye rubbing or prolonged use of contact lenses. Aponeurotic ptosis may also be caused or exacerbated by intraocular surgery or eyelid surgery (Fig 12-15).

Eyelids with aponeurotic defects characteristically have a high or an absent upper eyelid crease secondary to upward displacement or loss of the insertion of levator fibers into the skin. Thinning of the eyelid superior to the upper tarsal plate is often an associated

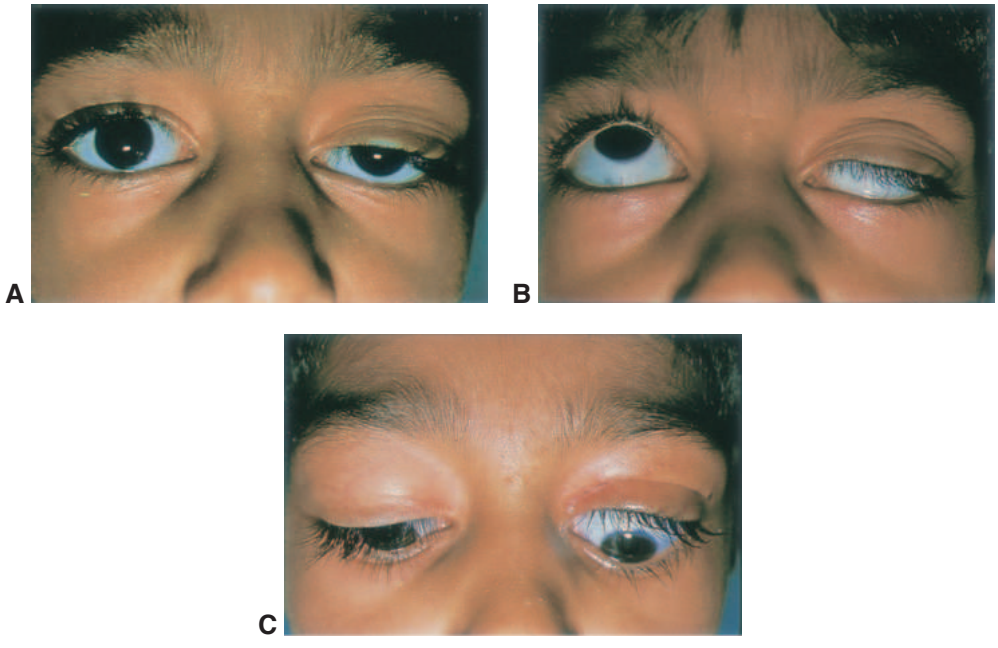

Figure 12-13 Left congenital ptosis. **A,** Patient's margin–reflex distance 1 is 6.0 mm OD and 0.5 mm OS (normal is 4–5 mm). **B,** Upgaze accentuates ptosis. **C,** Downgaze reveals lid lag. *(Courtesy of Robert C. Kersten, MD.)*

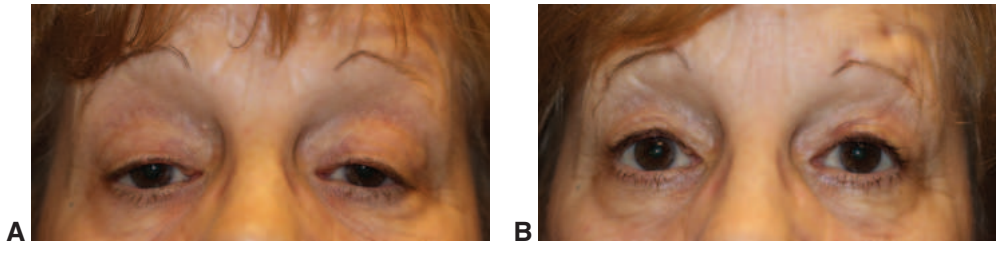

Figure 12-14 Bilateral myogenic ptosis from oculopharayngeal muscular dystrophy. **A,** Patient's margin–reflex distance 1 (MRD_1) is 0.5 mm in both eyes with significant brow recruitment pre-operatively. **B,** After frontalis suspension surgery, MRD_1 is 3.5 mm in both eyes. *(Courtesy of N. Grace Lee, MD.)*

finding. Because the levator muscle itself is healthy, levator function in aponeurotic ptosis is usually normal (15 mm). Acquired aponeurotic ptosis may worsen in downgaze, thus interfering with the patient's ability to read, as well as limiting the superior visual field. Table 12-1 compares acquired aponeurotic ptosis with congenital myogenic ptosis.

Neurogenic ptosis

Congenital conditions *Congenital neurogenic ptosis* is caused by innervational defects that occur during embryonic development. This condition is relatively rare and is most commonly associated with congenital cranial nerve III (CN III) palsy, congenital Horner syndrome, and Marcus Gunn jaw-winking syndrome.

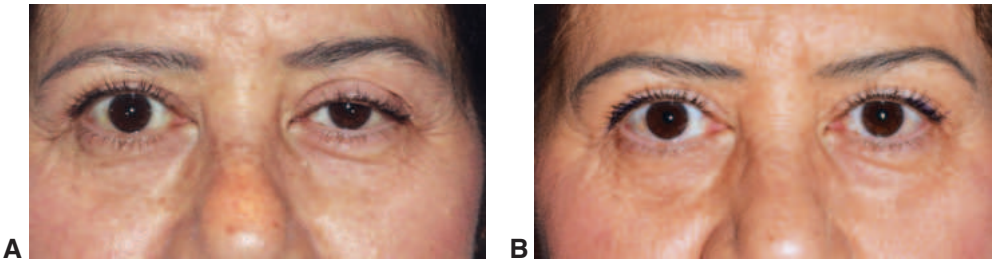

Figure 12-15 Aponeurotic ptosis. **A,** Aponeurotic ptosis of the left upper eyelid with left brow recruitment after cataract surgery. Similar aponeurotic ptosis can occur following various other intraocular and eyelid surgical procedures. **B,** After ptosis repair, the symmetry of the eyelid creases and folds has improved, as has the position of the left eyelid margin. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Table 12-1 Blepharoptosis Comparison

	Congenital Myogenic Ptosis	Acquired Aponeurotic Ptosis
Upper eyelid crease	Poorly formed	Higher than normal or absent
Levator function	Reduced	Near normal
Downgaze	Lid lag (increased palpebral fissure height)	Eyelid drop (decreased palpebral fissure height)

Congenital oculomotor nerve (CN III) palsy is manifested as ptosis together with the inability to elevate, depress, or adduct the globe. The pupils may also be dilated. This palsy may be partial or complete, but ptosis is very rarely an isolated finding. It is uncommon to find aberrant innervation in congenital CN III palsies. Management of strabismus and amblyopia is difficult in many cases of congenital CN III palsy. Treatment of the associated ptosis is also complicated, usually requiring a frontalis suspension procedure, which often leads to some degree of lagophthalmos. As a result of poor ocular motility, lagophthalmos, and poor postoperative eyelid excursion, postoperative management may be complicated by diplopia, exposure keratopathy, and corneal ulceration.

Congenital Horner syndrome is a manifestation of an interruption in the sympathetic nerve chain. It can cause mild ptosis associated with miosis, anhidrosis, and decreased pigmentation of the iris on the involved side. The mild ptosis of Horner syndrome results from an innervational deficit to the Müller muscle. Decreased sympathetic tone to the inferior tarsal muscle in the lower eyelid results in elevation of the lower eyelid, sometimes referred to as *reverse ptosis.* The combination of upper ptosis and lower eyelid elevation decreases the vertical palpebral fissure and may falsely suggest enophthalmos. Associated pupillary miosis is most apparent in dim illumination, when the contralateral pupil dilates more.

Congenital neurogenic ptosis may also be synkinetic. *Marcus Gunn jaw-winking syndrome* is the most common form of congenital synkinetic neurogenic ptosis (Video 12-4, Fig 12-16). In this synkinetic syndrome, the unilaterally ptotic eyelid elevates with jaw movements. The movement that most commonly causes elevation of the ptotic eyelid is

lateral mandibular movement to the contralateral side. This phenomenon is usually first noticed by the mother when she is feeding or nursing the baby. This synkinesis is thought to be caused by aberrant connections between the motor division of CN V and the levator muscle. Infrequently, this syndrome is associated with abnormal connections between CN III and other cranial nerves. Some forms of Duane retraction syndrome also cause elevation of a ptotic eyelid with movement of the globe. This congenital syndrome is also thought to result from aberrant nerve connections.

VIDEO 12-4 Marcus Gunn jaw-winking.
Courtesy of Pete Setabutr, MD.

Acquired conditions *Acquired neurogenic ptosis* results from interruption of normal development of innervation and is most often secondary to an acquired CN III palsy or Horner syndrome.

Delineation of the cause of acquired CN III (oculomotor) palsy is important. Distinction must be made between *ischemic* and *compressive* etiologies. Most acquired CN III palsies are *ischemic* and associated with diabetes mellitus, hypertension, or arteriosclerotic disease. Typically, *ischemic* acquired CN III palsies do not include pupillary abnormalities, may be associated with pain, and resolve spontaneously with satisfactory levator function

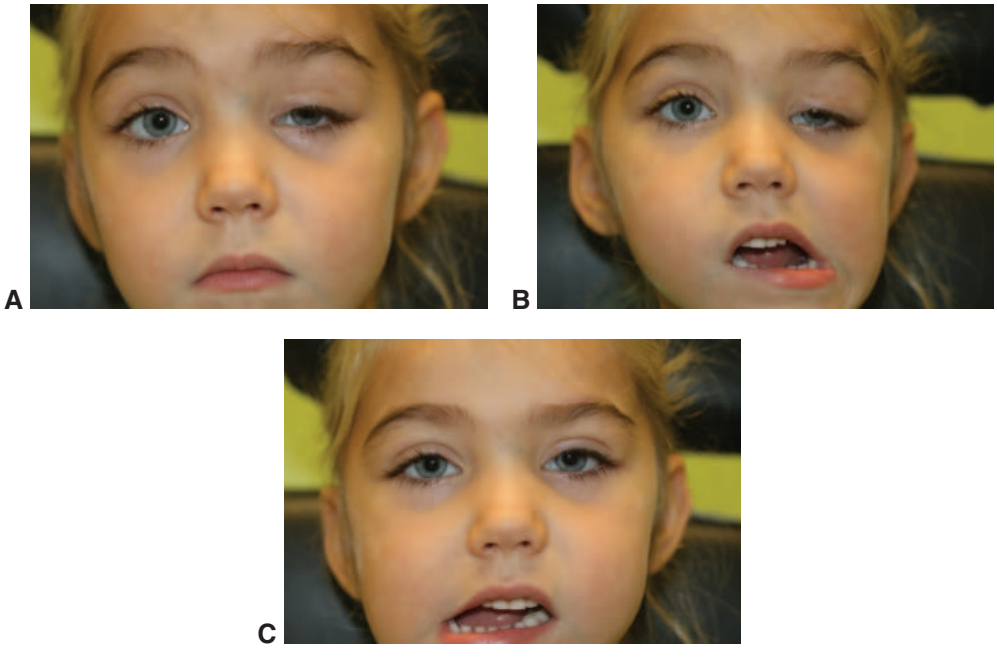

Figure 12-16 Marcus Gunn jaw-winking ptosis (synkinesis linking cranial nerve V to cranial nerve III). **A,** Relaxed position with ptosis of the left upper eyelid. **B,** When the mandible is moved to the left, the eyelid position remains low. **C,** Moving the mandible to the right elevates the left upper eyelid. *(Courtesy of Jill Foster, MD.)*

within 3 months. If a pupil-sparing CN III palsy fails to resolve spontaneously within 3–6 months, further workup for a compressive lesion is indicated. However, if a patient presents with a CN III palsy involving the pupil, an immediate workup (including neuroimaging) should commence in order to rule out a compressive neoplastic or aneurysmal lesion. Surgical correction of ptosis related to CN III palsy usually requires frontalis suspension and should be reserved for patients in whom strabismus surgery allows single binocular vision in a useful field of gaze. See BCSC Section 5, *Neuro-Ophthalmology,* for further discussion.

Temporary neurogenic ptosis can be caused by inadvertent diffusion of botulinum toxin into the levator muscle complex following therapeutic injection in the forehead or orbital region. The resultant ptosis usually resolves after several weeks.

Neuromuscular ptosis

Myasthenia gravis (MG) MG is an autoimmune disorder in which autoantibodies bind the acetylcholine receptors of the neuromuscular junction. Over 75% of patients will initially present with *ocular myasthenia gravis* (ie, effects isolated to the periocular musculature), with ptosis and diplopia being the most common presenting signs. Marked variability in the degree of ptosis experienced during the day and reports of diplopia should suggest ocular MG. Examination may reveal poor orbicularis strength, enhancement of ptosis (Hering's law of equal innervation), and variable sensorimotor examination (see Fig 12-12). Over 50% of patients with ocular MG will secondarily generalize within several years, which heightens the importance of patient counseling regarding potential risks for morbidity, including difficulty breathing. Approximately 10% of patients with generalized MG have an associated thymoma; thus, chest computed tomography (CT) should be considered for all patients with MG to rule out this lesion. Surgical thymectomy results in clinical improvement in 75% of cases of generalized MG and complete remission in 35% of cases. Other autoimmune disorders, such as thyroid eye disease (TED), may occur concomitantly in patients with myasthenia.

No single test for MG will detect all cases. Neuro-ophthalmologic consultation is useful in the evaluation and treatment of MG. Surgical treatment of ptosis should be delayed until medical management of MG is optimized. Because of the variability of levator function, frontalis suspension may be considered. See BCSC Section 5, *Neuro-Ophthalmology,* for further discussion.

Mechanical ptosis

In mechanical ptosis, the upper eyelid is weighed down by a mass or swelling in the eyelid or orbit (Fig 12-17). It may be caused by a congenital mass lesion such as a plexiform neurofibroma or hemangioma, or by an acquired lesion such as a large chalazion or skin carcinoma. Postsurgical or posttraumatic edema may also cause temporary mechanical ptosis.

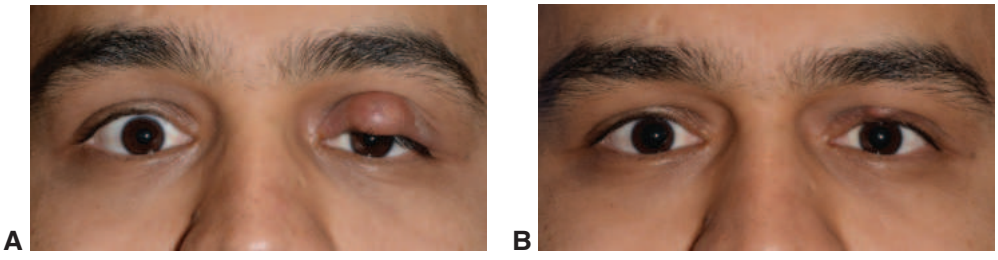

Figure 12-17 Mechanical ptosis. **A,** Chalazion of the left upper eyelid causing mechanical ptosis. **B,** Ptosis is improved after incision and drainage of the chalazion. *(Courtesy of Bobby S. Korn, MD, PhD.)*

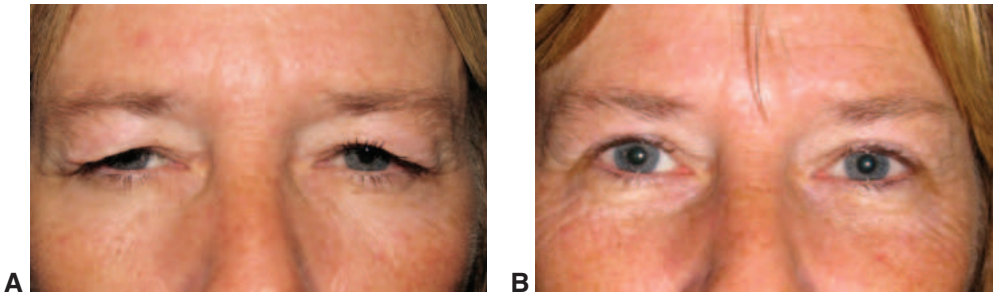

Figure 12-18 Bilateral upper eyelid dermatochalasis. **A,** Patient with dermatochalasis and pseudoptosis of both upper eyelids. **B,** Clearance of the visual axis is achieved through blepharoplasty alone. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Traumatic ptosis

Trauma to the levator aponeurosis or the levator palpebrae superioris muscle may cause ptosis through myogenic, aponeurotic, neurogenic, or mechanical defects. An eyelid laceration that exposes preaponeurotic fat indicates that the orbital septum has been violated and suggests possible damage to the levator muscle and/or aponeurosis. Exploration of the levator and its repair may be indicated in this situation. Orbital and neurosurgical procedures can also lead to traumatic ptosis. Since such ptosis may resolve or improve spontaneously, the ophthalmologist typically observes the patient for an extended period before considering surgical intervention.

Pseudoptosis

Pseudoptosis, which gives the appearance of a drooping eyelid, should be differentiated from true ptosis. An eyelid may appear to be abnormally low in various conditions, including brow ptosis, enophthalmos, silent sinus syndrome, microphthalmia, anophthalmia, phthisis bulbi, synkinesis, and superior sulcus defect secondary to trauma or other causes. Contralateral upper eyelid retraction, for instance, from TED, may also simulate ptosis. The term *pseudoptosis* is also sometimes used to describe *dermatochalasis,* the condition in which excess upper eyelid skin overhangs the eyelid margin (Fig 12-18).

Management

Ptosis repair is a challenging and often-debated topic. The patient's ocular, medical, and surgical history help determine whether surgical repair is appropriate. Specifically, the surgeon should be aware of any history of dry eye, TED, neuromuscular disorder, previous eye or eyelid surgery or neurotoxin injections, and periorbital trauma.

Ptosis that causes amblyopia, significant superior visual field loss, or difficulty with reading is considered to be a *functional* problem. In other instances, ptosis may be considered a *cosmetic* issue. Because ptosis repair is often an elective surgical procedure, it is particularly important for the surgeon to review the cosmetic and functional consequences of the procedure as well as potential risks.

Ptosis repair surgery should be directed toward correction of the underlying pathologic condition. The 3 categories of surgical procedures most commonly used in ptosis repair are

- external (transcutaneous) levator advancement
- internal (transconjunctival) levator/tarsus/Müller muscle resection
- frontalis muscle suspension or advancement

The patient's amount and type of ptosis and degree of levator function are the most common determining factors in selecting the type of corrective surgery. In patients with good levator function, surgical correction is generally directed toward the levator aponeurosis. However, if levator function is poor or absent, frontalis muscle suspension techniques are preferred.

External (transcutaneous) levator advancement surgery is most commonly used when levator function is normal and the upper eyelid crease is high (Video 12-5). In these patients, the levator muscle itself is normal, but the levator aponeurosis is stretched or disinserted, thus requiring advancement. The levator aponeurosis is approached externally through an upper eyelid crease incision and is advanced to the superior tarsal border. The patient's cooperation is elicited to open the eyelids to obtain optimal height and contour. This surgery can also be accomplished through a small incision no longer than 1 cm (Fig 12-19).

VIDEO 12-5 External levator advancement ptosis repair.
Courtesy of Jill Foster, MD; Dan Straka, MD; and Craig Czyz, DO.

The *internal (transconjunctival)* approach to ptosis repair is directed toward the Müller muscle, the tarsus, or the levator aponeurosis or muscle (Video 12-6). A comparison of MRD_1 before and after the instillation of 2.5% phenylephrine may be performed to identify patients who are candidates for the internal approach (Fig 12-20A, B). The Müller muscle–conjunctival resection procedure (MMCR) was traditionally used for repair of minimal ptosis (2 mm or less) (Fig 12-20C, D). However, recent evidence supports its use in cases of severe ptosis. The procedure is generally considered useful for maintaining the preoperative eyelid contour. The *Fasanella-Servat* ptosis repair procedure, which is used for small amounts of ptosis, includes removal of the superior tarsus with the conjunctiva and Müller muscle.

Crouch, MD.)*

Many patients with significant ptosis use the frontalis muscle in an attempt to raise the eyelid and clear the visual axis. In *frontalis suspension* surgery (Fig 12-21), which is performed when levator function is poor or absent, the eyelid is suspended directly from the frontalis muscle so that movement of the brow is efficiently transmitted to the eyelid. Thus, the patient is able to elevate the eyelid by using the frontalis muscle to lift the brow. Several sling options exist for frontalis suspension; they can be grouped as autogenous, allogenic, or synthetic.

Autogenous tensor fascia lata has shown good long-term results but requires the patient to undergo additional surgery related to tissue harvesting. Generally, autogenous fascia lata can be used in patients who are at least 3 years old or weigh 35 pounds or more.

Allogenic slings, such as banked fascia lata, can be obtained from a variety of sources and spares the patient harvesting surgery. However, this material may incite inflammation and has the theoretical potential to transmit infectious disease.

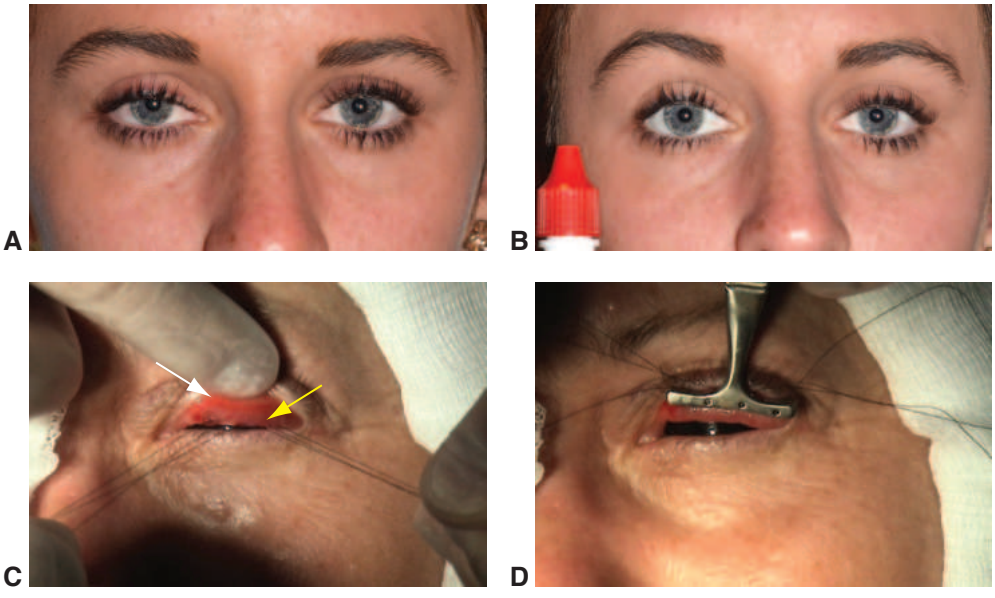

Figure 12-20 Internal approach to ptosis repair. **A,** Patient with ptosis of the right upper eyelid. **B,** Improvement of ptosis after instillation of 2.5% phenylephrine hydrochloride. **C,** Intraoperative photograph showing tarsus *(white arrow),* conjunctiva, and Müller muscle *(yellow arrow).* **D,** Ptosis clamp securing conjunctiva and Müller muscle prior to excision. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Synthetic materials such as silicone rods and polyfilament (cable-type 3-0) sutures are commonly used. No tissue harvesting is involved, and this option allows for easier adjustment or removal, if necessary (Video 12-7).

VIDEO 12-7 Frontalis suspension with silicone rods.
Courtesy of Richard C. Allen, MD, PhD.

The *frontalis muscle advancement flap* procedure, in which the muscle itself is brought inferiorly to the eyelid, can also be utilized for myogenic ptosis; this obviates the placement of an autogenous, allogenic, or synthetic sling.

There is some controversy about whether bilateral frontalis suspension should be performed in patients with unilateral congenital ptosis. A bilateral procedure may improve the patient's symmetry and stimulate the need to utilize the frontalis muscle to lift the eyelids, but it subjects the normal eyelid to surgical risks. The decision of whether to modify a normal eyelid in an attempt to gain symmetry should be discussed by the surgeon and the patient or the patient's caregiver.

Complications

Undercorrection is the most common complication of ptosis repair. Astute judgment is required to differentiate this from a mechanical ptosis caused by early postoperative edema. Other potential complications include overcorrection, unsatisfactory eyelid contour, scarring, wound dehiscence, eyelid crease asymmetry, conjunctival prolapse, tarsal eversion, implant extrusion, and lagophthalmos with exposure keratopathy. This last condition is usually temporary, but it requires treatment with lubricating eyedrops or ointments until it resolves. Achieving symmetry between the 2 eyelids is a difficult aspect of ptosis repair, and some ptosis surgeons use adjustable suture techniques or early adjustment in the office during the first 2 postoperative weeks, when indicated.

Nonsurgical options

Temporary ptosis correction by approximately 1–2 mm can be achieved with a prescription for a 0.1% oxymetazoline hydrochloride ophthalmic solution eyedrop, which is approved by the US Food and Drug Administration for this purpose. Studies have shown that its effects can last 8–14 hours. Patients may experience tachyphylaxis with oxymetazoline after repetitive use.

Ptosis eyelid crutches can be utilized for severe ptosis in patients who are incapable of undergoing surgery. The crutches, which are attached to the top rim of the eyeglasses, compress the eyelid near the superior orbital rim, mechanically elevating the eyelid (Fig 12-22).

Eyelid Retraction

Eyelid retraction is the superior or inferior displacement of the upper or lower eyelids, respectively, that exposes sclera between the limbus and the eyelid margin (Fig 12-23). It can be unilateral or bilateral. Lower eyelid retraction may also be a normal anatomic variant in patients who have shallow orbits or certain genetic orbital or eyelid characteristics. Retraction of the eyelids often leads to lagophthalmos and exposure keratopathy, with consequences ranging from ocular irritation and discomfort to vision-threatening corneal exposure.

Causes

The causes of eyelid retraction may be local, systemic, or to do with the central nervous system. The most common are TED, recession of the vertical rectus muscles, aggressive tissue removal during blepharoplasty, and overcompensation for a contralateral ptosis (Hering's law of equal innervation).

Thyroid eye disease is the most common cause of both upper and lower eyelid retraction, as well as unilateral or bilateral proptosis. Because proptosis commonly coexists with and may mimic eyelid retraction (and vice versa) in patients with TED, these conditions are evaluated through eyelid measurements and exophthalmometry. A common finding in TED-related eyelid retraction is *temporal flare.* In this condition, the eyelid retraction is more severe laterally than medially, resulting in an abnormal upper eyelid contour that appears to flare upward along the lateral half of the eyelid margin. See Chapter 4 for a more extensive discussion of TED.

Iatrogenic eyelid retraction may be induced by recession of the vertical rectus muscles, owing to anatomic connections between the superior rectus and the levator palpebrae superioris muscle in the upper eyelid and between the inferior rectus muscle and capsulopalpebral fascia in the lower eyelid. Another iatrogenic cause of eyelid retraction, especially of the lower eyelids, is excessive resection of skin, middle lamellar scarring, and untreated lower eyelid laxity during cosmetic lower blepharoplasty. Correction may require any combination of lower eyelid tightening, midface-lifting, full-thickness skin grafting, or spacer grafting. Conservative excision of skin in lower blepharoplasty, along with concomitant correction of any lower eyelid laxity, minimizes the risk of this problem.

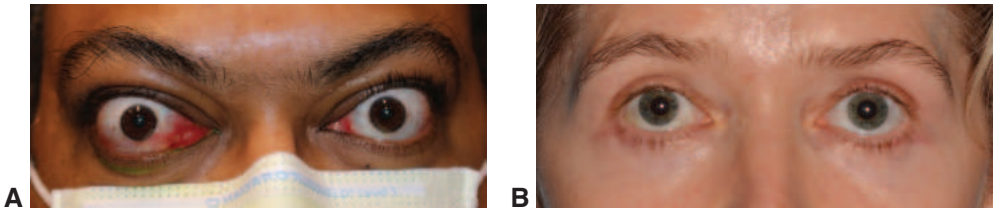

Figure 12-23 Upper and lower eyelid retraction. **A,** Retraction secondary to thyroid eye disease (TED). **B,** Retraction resulting from excessive skin removal and middle lamellar scarring after cosmetic blepharoplasty. *(Part A courtesy of N. Grace Lee, MD; part B courtesy of Bobby S. Korn, MD, PhD.)*

Other etiologies include *Parinaud syndrome,* an example of eyelid retraction caused by a lesion that affects the dorsal midbrain. *Congenital* eyelid retraction occurs as a rare, isolated entity.

Management

Treatment of eyelid retraction is based on its severity as well as underlying etiologic factors. In patients with mild eyelid retraction, artificial tears, lubricants, and ointments may be sufficient to protect the cornea and minimize symptoms. The use of moisture chamber goggles and PROSE (Prosthetic Replacement of the Ocular Surface Ecosystem) lenses may also be indicated. Mild eyelid retraction resulting from lower blepharoplasty or TED may resolve spontaneously over time. A variety of surgical techniques have been developed to correct eyelid retraction that is persistent and/or sight threatening. Except in cases of severe exposure keratopathy, surgical intervention is undertaken only after serial measurements have established stability of the eyelid position. Upper eyelid retraction can be corrected by excision or recession of the Müller muscle (anterior or posterior approach), recession of the levator aponeurosis with or without hang-back sutures or another spacer (Fig 12-24 A, B), measured myotomy of the levator muscle, or full-thickness transverse blepharotomy (Fig 12-24 C, D).

If the patient has lateral flare, a small eyelid-splitting lateral tarsorrhaphy, combined with recession of the upper and lower eyelid retractors, can improve the upper eyelid contour; however, this technique may limit the patient's lateral visual field.

As with correction of the upper eyelids, treatment of lower eyelid retraction is directed by the underlying etiologic factors. *Anterior lamellar deficiency* (eg, excess skin resection from blepharoplasty) requires recruitment of vertical skin by means of a midface-lift and/or addition of skin with a full-thickness skin graft. *Middle lamellar deficiency* (eg, posttraumatic septal scarring) requires scar release and possible placement of a spacer graft. *Posterior lamellar deficiency* from congenital scarring or conjunctival shortage (eg, mucous membrane pemphigoid) may require a full-thickness mucous membrane graft.

Severe retraction of the lower eyelids, common in patients with TED, may require a spacer graft between the lower eyelid retractors and the inferior tarsal border. Autogenous auricular cartilage, hard-palate mucosa, free tarsal grafts (see Figure 12-24 C, D), acellular dermal matrix, and dermis fat are common spacer materials. It is often necessary to perform some type of horizontal eyelid or lateral canthal tightening or elevation as well.

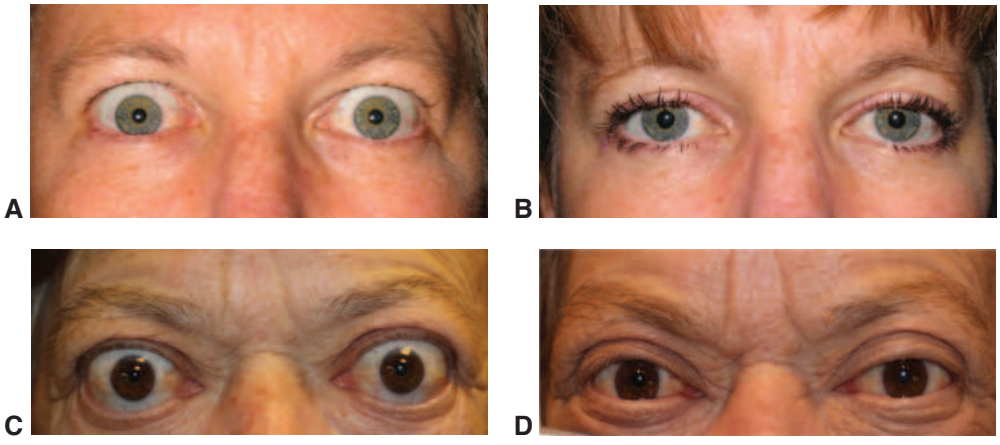

Figure 12-24 Bilateral upper and lower eyelid retraction in TED. **A,** Preoperative appearance of upper eyelid retraction. **B,** Same patient after upper eyelid retractor recession. **C,** Preoperative appearance of upper and lower eyelid retraction. **D,** Same patient after lower eyelid recession with upper eyelid tarsal graft and upper eyelid full-thickness blepharotomy. *(Parts A and B courtesy of Bobby S. Korn, MD, PhD; parts C and D courtesy of N. Grace Lee, MD.)*

However, because horizontal tightening of the lower eyelid in a patient with proptosis may exacerbate the eyelid retraction, use of this technique requires caution. Many surgeons believe that significant upper and lower eyelid retraction in the setting of proptosis is optimally treated with orbital decompression prior to eyelid retraction surgery because the decrease in exophthalmos may improve the severity of eyelid retraction.

For patients who are poor surgical candidates or may require a temporizing measure until adequately stable for surgery, nonsurgical options include neurotoxin or steroid injection to the upper eyelid retractors. These injections can be placed anteriorly through the skin or posteriorly through the conjunctiva.

Facial Paralysis

Paralytic Ectropion

Paralytic ectropion usually follows CN VII paralysis or palsy. Typically, concomitant upper eyelid lagophthalmos is present secondary to paralytic orbicularis dysfunction. Poor blinking and eyelid closure lead to chronic ocular surface irritation from corneal exposure as well as inadequate tear film replenishment and distribution. Chronically stimulated reflex tear secretion, atonic eyelids, and lacrimal pump failure account for patients' frequent reports of tearing.

Neurologic evaluation may be needed to determine the cause of CN VII paralysis. In cases resulting from stroke or intracranial surgery, clinical evaluation of corneal sensation is indicated because neurotrophic keratopathy combined with paralytic lagophthalmos increases the risk of corneal exposure and perforation.

Lubricating drops, viscous tear supplementation, ointments, taping of the temporal half of the lower eyelid, or moisture chamber goggles can be used. Such measures may be the only treatment necessary, especially for temporary paralysis. In select patients with long-term or permanent paralysis, tarsorrhaphy, medial or lateral canthoplasty, suspension procedures, and horizontal tightening procedures are useful.

Tarsorrhaphy can be performed either medially or laterally. An adequate temporary tarsorrhaphy (1–3 weeks) can be achieved with placement of nonabsorbable sutures between the upper and lower eyelid margins. A "temporary tarsorrhaphy" can also be created by injection of botulinum toxin into the levator muscle. Permanent tarsorrhaphy involves de-epithelialization of the upper and lower eyelid margins, avoiding the lash follicles. Absorbable or nonabsorbable sutures are then placed to unite the raw surfaces of the upper and lower eyelids (Fig 12-25).

Occasionally, a fascia lata or silicone suspension sling of the lower eyelid may be indicated. Vertical elevation of the lower eyelid is useful in reducing exposure of the inferior cornea. This elevation may be accomplished through recession of the lower eyelid retractors, combined with use of a spacer graft. Surgical midface elevation can also play an important role in lower eyelid support.

Upper Eyelid Paralysis

Upper eyelid loading remains the most commonly performed procedure for the treatment of paralytic lagophthalmos. The appropriate weight can be selected through a process of preoperatively taping eyelid weights of different sizes to the upper eyelid skin to determine which one best achieves adequate relaxed eyelid closure with minimal ptosis in primary gaze. After the weight is selected, it is inserted through an upper eyelid crease incision and is either sutured to the anterior surface of the tarsal plate (Fig 12-26) or behind the orbital septum; the latter may avoid thickening of the pretarsal area. If orbicularis function

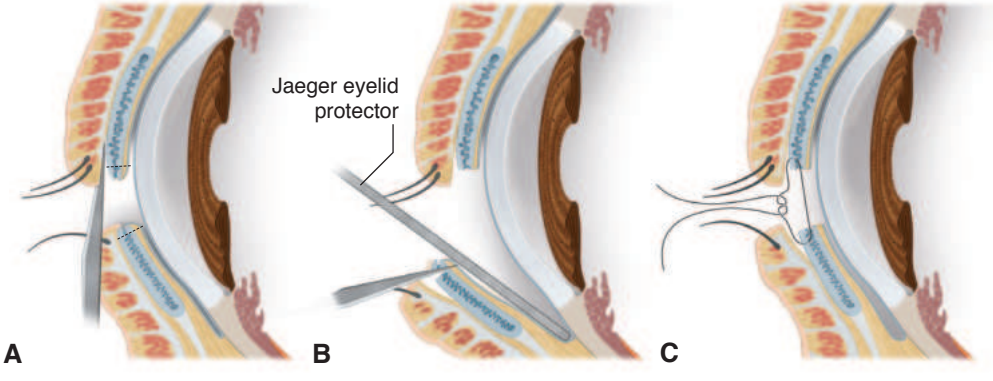

Figure 12-25 Tarsorrhaphy. **A,** The eyelid is split between the anterior and posterior lamellae 2–3 mm deep. **B,** Epithelium is carefully removed along the upper and lower eyelid margins; the eyelash follicles are avoided. **C,** The raw surfaces are then joined with absorbable sutures. *(Illustration by Mark Miller.)*

Figure 12-26 Left upper eyelid loading with a thin-profile gold weight anterior to the tarsal plate. *(Courtesy of Cat N. Burkat, MD.)*

returns, the weight can be removed easily. Weights made of gold and platinum allow for magnetic resonance imaging (7 Tesla or less). Nonsurgical options include eyelid splints and use of hyaluronic acid gel injection in the pretarsal and preseptal plane; these function as temporary weights in the upper eyelid. Brow ptosis repair and blepharoplasty, in addition to facial volume augmentation, may be considered after improvement of corneal exposure.

Facial Dystonia

Benign Essential Blepharospasm

Benign essential blepharospasm (BEB) is a bilateral focal dystonia that affects approximately 30 of every 100,000 people. The condition is characterized by increased blinking and involuntary spasms of the periocular protractor muscles (Video 12-8). The spasms generally start as mild twitches and progress over time to forceful contractures. Other muscles of the face may also be involved with blepharospasm. Unlike hemifacial spasm, BEB typically abates during sleep. The involuntary episodes of forced blinking or contracture may severely limit the patient's ability to drive, read, or perform activities of daily living. Women are affected more frequently than men. The age of onset is usually older than 40 years. BEB is a clinical diagnosis, and neuroimaging is rarely indicated in the workup. BEB must be differentiated from *reflex blepharospasm,* which can occur secondary to dry eye syndrome and other medical conditions.

VIDEO 12-8 Benign essential blepharospasm.
Courtesy of Pete Setabutr, MD.

The cause of BEB is unknown; however, it is probably of central origin, in the basal ganglia. BEB can be managed by medical or surgical approaches. Neurotoxin injections are the primary treatment for blepharospasm. (See BCSC Section 5, *Neuro-Ophthalmology.*)

Botulinum toxin injection

Repeated periodic injection of one of the botulinum toxin type A formulations is the treatment of choice for BEB (Fig 12-27). Injection of these agents at therapeutic doses results in chemical denervation (also called *chemodenervation*) and localized muscle paralysis. Botulinum toxin injection is typically effective, but the improvement is temporary. Average onset of action is in 2–3 days, and average peak effect occurs at about 7–10 days after injection. Duration of effect also varies but is typically 3–4 months, at which point recurrence of the spasms and need for reinjection is anticipated. Complications associated with botulinum toxin injection include bruising, blepharoptosis, ectropion, epiphora, diplopia, lagophthalmos, and corneal exposure. These adverse reactions are usually transient and result from spread of the toxin to adjacent muscles. Tachyphylaxis can also develop.

Surgical myectomy

Treatment with surgical myectomy is reserved for patients with severe spasms who do not respond adequately to botulinum therapy. Meticulous removal of the orbital and palpebral orbicularis muscle in the upper (and sometimes lower) eyelids can be an effective and permanent treatment for blepharospasm. Complications of surgical myectomy include lagophthalmos, chronic lymphedema, and periorbital contour deformities. Limited upper eyelid protractor myectomy is helpful in patients with less severe disease. Recurrence of spasm is not uncommon after myectomy, and treatment with reduced dosage of botulinum toxin is indicated.

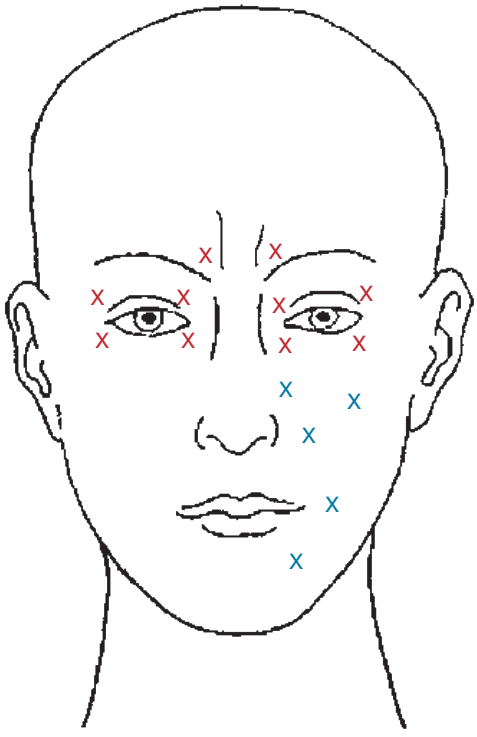

Figure 12-27 Injection patterns of botulinum toxin type A for benign essential blepharospasm *(red)* and hemifacial spasm *(unilateral red sites plus blue).* *(Modified from Dutton JJ, Fowler AM. Botulinum toxin in ophthalmology.* Focal Points: Clinical Modules for Ophthalmologists. *American Academy of Ophthalmology; 2007, module 3.)*

Many patients with BEB have an associated dry eye condition that may be aggravated by any treatment modality that decreases eyelid closure. Artificial tears, ointments, punctal plugs or occlusion, moisture chamber goggles and tinted (FL-41) spectacle lenses may help minimize discomfort from ocular surface problems.

Muscle relaxants and sedatives

Muscle relaxants and sedatives are rarely effective in the primary treatment of BEB. Oral medications such as orphenadrine, lorazepam, and clonazepam are sometimes effective in suppressing mild cases of BEB, prolonging the interval between botulinum toxin injections, or helping to dampen oromandibular dystonia associated with BEB. Psychotherapy has little or no value for the patient with blepharospasm.

Hemifacial Spasm

Blepharospasm should be differentiated from hemifacial spasm (HFS). HFS is characterized by intermittent synchronous gross contractures of the entire side of the face and is rarely bilateral (Video 12-9). HFS often begins in the periocular region and then progresses to involve the entire half of the face. Unlike BEB, HFS persists during sleep.

VIDEO 12-9 Hemifacial spasm.
Courtesy of Pete Setabutr, MD.

HFS is often associated with ipsilateral facial nerve weakness. In most cases, HFS is the result of a vascular compression of the facial nerve root exit zone at the brain stem. Magnetic resonance imaging (MRI) often reveals the ectatic vessel. MRI can also help rule out other cerebellopontine angle lesions that may be the cause in less than 1% of cases. Neurosurgical decompression of the facial nerve may be curative in HFS, but it carries significant associated risks. Periodic injection of botulinum toxin is a commonly used, effective treatment option for HFS (see Fig 12-27). Oral medications, including drugs with membrane-stabilizing properties such as carbamazepine and clonazepam, are used less frequently because of their low efficacy.

Aberrant regeneration after facial nerve palsy may also present with hemifacial contracture and synkinetic facial movements. The history (eg, previous Bell palsy, trauma) and clinical examination are distinctive. Neuroimaging is indicated to rule out a mass lesion. Functionally troublesome synkinetic facial movements often respond well to botulinum toxin injection.

Involutional Periorbital Changes

Dermatochalasis

Dermatochalasis refers to redundancy of eyelid skin and is often associated with orbital fat prolapse (see Fig 12-18). Patients with significant dermatochalasis of the upper

eyelids may report a heavy feeling around the eyes, brow-ache or headache, eyelashes in the visual axis, and reduction in the superior visual field. Dermatochalasis is often exacerbated by brow ptosis. Lower eyelid dermatochalasis is considered a cosmetic issue unless the excess skin and prolapsed fat are so severe that the patient cannot be fitted with bifocals.

Blepharochalasis

Although blepharochalasis is not an involutional change, it is included in this discussion because it can resemble, and must be differentiated from, dermatochalasis. Blepharochalasis is a rare familial variant of angioneurotic edema. It occurs most commonly in women younger than 40 years and is characterized by idiopathic episodes of inflammatory edema of the eyelids. As a result of recurrent bouts of inflammation and edema, the eyelid skin becomes thin and wrinkled, simulating the appearance of dermatochalasis. In addition, true ptosis, herniation of the orbital lobe of the lacrimal gland, atrophy of the orbital fat pads, and prominent eyelid vascularity may be associated with blepharochalasis. Surgical repair of the eyelid skin changes and ptosis associated with blepharochalasis may be complicated by repeated episodes of inflammation and edema.

Blepharoplasty

Upper Eyelid

Upper blepharoplasty is one of the most commonly performed oculoplastic procedures (Video 12-10). Involutional skin and structural changes often begin in the periorbital area, and they can obstruct the superior visual field. Blepharoplasty is frequently performed to relieve this obstruction. Brow ptosis may also play a role and may need to be addressed. Functional indications for blepharoplasty are documented by means of external photography and visual field testing with and without manual eyelid elevation. Patients undergoing blepharoplasty for cosmetic reasons may have different expectations than those undergoing functional blepharoplasty. Thus, a thorough preoperative discussion of the anticipated results is critical to preoperative planning.

VIDEO 12-10 Upper blepharoplasty.
Courtesy of Jill Foster, MD; Dan Straka, MD; and Craig Czyz, DO.

Lower Eyelid

Lower blepharoplasty is most commonly performed for cosmetic indications. However, some patients undergo this procedure because of functional concerns such as difficulty reading, which can occur when prolapsed orbital fat and skin cover the bifocal spectacle segment. See Chapter 13 for more details regarding management.

Preoperative Evaluation

Evaluation of any potential blepharoplasty patient includes the following:

- complete ocular examination that includes visual acuity testing and documentation
- history of prior periocular surgery or injections
- identification of amount and areas of excess skin, as well as the amount and contours of prolapsed orbital fat, in the upper and lower eyelids
- presence or absence of lagophthalmos, which can lead to postoperative dryness and exposure keratopathy
- evaluation of tear secretion or the tear film, which may be carried out through Schirmer testing, tear breakup time assessment, or assessment of the adequacy of the tear meniscus
- photographic documentation

Upper blepharoplasty

In addition to the assessments above, the examination before upper blepharoplasty includes the following elements:

- visual field testing to determine the presence and degree of superior visual field defects (if needed for documentation)
- evaluation of the forehead and eyebrows (including brow height and contour) to detect forehead and brow ptosis; the surgeon should make careful observations when the patient's facial and brow musculature is relaxed
- notation of the position of the upper eyelid crease
- evaluation for concomitant upper eyelid ptosis

Lower blepharoplasty

See Chapter 13 for discussion of lower blepharoplasty.

Techniques

A thorough working knowledge of periorbital and eyelid anatomy (discussed in Chapter 9) is essential for successful blepharoplasty. Just as the brow and glabellar areas affect the upper eyelids, the midfacial structures influence the position, tone, contour, and function of the lower eyelids and must be considered in surgical planning.

Surgical preparation involves marking excess skin for excision prior to infiltration of local anesthetic. The surgeon can determine the amount of skin to be excised by grasping the upper eyelid skin with toothless forceps and identifying the amount of redundancy *(pinch technique)*. To avoid excessive skin removal, the surgeon usually leaves at least 20 mm of skin remaining between the inferior border of the brow and the upper eyelid margin (Fig 12-28).

Upper blepharoplasty

Upper blepharoplasty begins with the surgeon incising along the lines marked on the upper eyelid. The surgeon removes skin and then may selectively remove orbicularis and a conservative amount of orbital fat to reshape the upper eyelid. Adjunctive procedures to re-form or create a new eyelid crease (Fig 12-29) and reposition the lacrimal gland may be necessary.

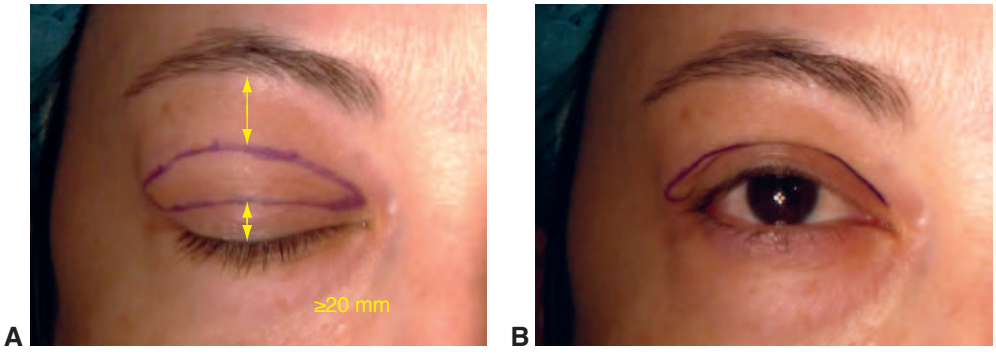

Figure 12-28 Preoperative marking. **A,** Typical skin marking for upper eyelid blepharoplasty. After skin marking, there should be at least 20 mm of remaining upper eyelid skin *(sum of the distance indicated by the arrows).* **B,** The upper and lower markings are superimposed when the eye is open. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Complications

Although it is rare, *loss of vision* is the most dreaded complication of blepharoplasty and is usually associated with *lower* blepharoplasty. Such blindness is typically thought to occur secondary to postoperative retrobulbar hemorrhage, with the increased intraorbital pressure causing ischemic compression of the ciliary arteries, which supply the optic nerve. Other mechanisms of injury include ischemia caused by excessive surgical retraction or constriction of retrobulbar blood vessels in response to epinephrine in the local anesthetic. Orbital hemorrhage may result from injury to the deeper orbital blood vessels or from bleeding anteriorly. Risk factors for this complication include hypertension, blood dyscrasias, and anticoagulant use. Postoperative pressure dressings should be avoided: they increase orbital pressure and obscure underlying problems.

Patients should be observed immediately postoperatively to detect possible orbital hemorrhage. Those with significant pain, marked asymmetric swelling, or new proptosis should be evaluated. In addition, visual dimming or darkness or significant or asymmetric blurred vision following eyelid surgery may indicate orbital hemorrhage and should be assessed and treated immediately (see the discussion of orbital compartment syndrome in Chapter 6 for management).

Excessive removal of skin is a complication that can lead to lagophthalmos as well as cicatricial ectropion or eyelid retraction. Topical lubricants and massage may be helpful

for managing mild postoperative lagophthalmos, retraction, or ectropion, all of which may resolve over time. Injectable steroids or 5-fluorouracil can be used if a deep cicatrix contributes to the retraction. Severe cases require the use of free skin grafts, spacer grafts, lateral canthoplasty, or surgical release of scar tissue or eyelid retractors.

Brow Ptosis

Loss of elastic tissues and facial volume, as well as involutional changes of the forehead skin, lead to drooping of the forehead and eyebrows. This condition is known as *brow ptosis.* Severe brow ptosis may also result from facial nerve palsy. Brow ptosis frequently accompanies dermatochalasis and must be recognized as a factor that contributes to the appearance of aging in the periorbital area. If severe, brow ptosis may impinge on the superior visual field (Fig 12-30). The patient often involuntarily compensates for this condition by using the frontalis muscle to elevate the eyebrows. Such chronic contracture of the frontalis muscle often leads to brow-ache, headache, and prominent static transverse forehead rhytids.

In most individuals, the brow is located at the level of or above the superior orbital rim. Generally, the female brow is higher and more arched than the typical male brow. The brow is considered ptotic when it falls below the superior orbital rim.

Management

Brow ptosis should be recognized and treated prior to or concomitant with the surgical repair of coexisting dermatochalasis of the eyelids. Because brow elevation reduces the amount of dermatochalasis present, it should be performed or simulated first when combined with upper blepharoplasty. Aggressive upper blepharoplasty alone in a patient with concomitant brow ptosis leads to further depression of the brow. Brow ptosis may be corrected with browpexy, direct brow elevation, or an endoscopic or pretrichial brow- and forehead-lift. See the section Forehead Rejuvenation in Chapter 13 for details on endoscopic and open brow- and forehead-lifts.

Browpexy

Browpexy is used for treatment of mild brow ptosis and is performed through an upper eyelid blepharoplasty incision. The sub-brow tissues are resuspended with sutures to the

Figure 12-30 Brow ptosis causing functional impairment in the patient's peripheral visual field. *(Courtesy of Bobby S. Korn, MD, PhD.)*

frontal bone periosteum above the orbital rim as part of a blepharoplasty. Although this procedure provides minimal improvement in brow position, it can help prevent the retro–orbicularis oculi fat from descending into the eyelid (See Chapter 9, Fig 9-22).

Direct brow elevation

The brows can be elevated with incisions placed at the upper edge of the brow hairs. This is an effective technique for treatment of brow ptosis and is particularly useful for men and women with lateral brow ptosis. When direct eyebrow elevation is used across the entire brow, it may result in an arch or displeasing scar. Sensory paresthesias may be an adverse effect of the direct brow procedure.

CHAPTER 13

Facial Rejuvenation

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- Facial rejuvenation techniques vary and include both nonsurgical and surgical interventions.
- Laser skin resurfacing is designed to reduce wrinkles and enhance the texture and appearance of the facial and periorbital skin.
- The US Food and Drug Administration (FDA) has approved the use of botulinum toxin to temporarily reduce wrinkles in the glabellar area and diminish the lateral canthal lines (crow's-feet), and the forehead.
- Complications from facial fillers include regional soft-tissue necrosis and central retinal artery occlusion from intravascular injection, as well as lumps, bruising, infection, and nodule formation.
- Rhytidectomy involves surgical management of the jowls and neck, including liposuction with or without platysmaplasty.

Pathogenesis of the Aging Face

An individual's facial contours and appearance are derived from soft tissue draped over underlying bone. The soft-tissue component consists of skin, subcutaneous fat, muscle, deeper fat pads, and fascial layers. The underlying structural element is composed of bone, cartilage, and teeth.

As the face ages, the soft-tissue component descends, and the bone component loses mass. With these changes, relatively more soft tissue hangs from its attachments to the bone. Loss of subcutaneous fat, skin atrophy, and descent of facial fat pads compound this facial sagging. Around the eyes, the lateral brow typically descends more than the medial brow, which leads to temporal hooding. The orbital septum attenuates, allowing fat to prolapse forward. In the lower eyelid, midface descent produces the skeletonization of the infraorbital rim and increases the prominence of the orbital fat. Sagging of the platysma muscle in the neck posterior to the mandibular ligament gives rise to jowling (Fig 13-1).

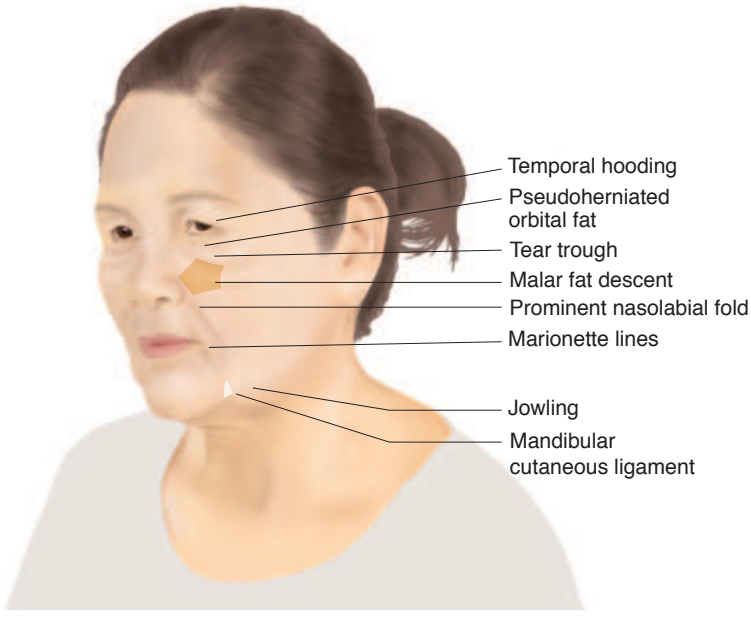

Figure 13-1 Etiologies of aging. Facial changes include temporal hooding from lateral brow descent and dermatochalasis; attenuation of the septum in the lower eyelid, causing pseudoherniated orbital fat pads and a prominent orbitomalar groove (or tear trough); and descent of malar fat, which accentuates the nasolabial fold. Weakening of the mandibular cutaneous ligament and descent of the platysma and subcutaneous jowl fat lead to marionette lines. *(Illustration by Cyndie C. H. Wooley.)*

Physical Examination of the Aging Face

Much of the surgeon's appraisal of the aging face can be performed through close observation during the introduction and history phase of the initial meeting. The surgeon should observe the patient's hairstyle, including the presence or absence of bangs, hair thickness, and the height of the hairline; the use of the frontalis; the position of the brow; the texture and quality of the facial skin; and the presence and location of rhytids, telangiectasias, pigmentary dyschromia, and expressive furrows. As a part of the assessment, the physician should be mindful of the patient's expectations and whether they can be met with either a minimally invasive procedure or surgery.

If chemical peeling or laser skin resurfacing is being considered, the surgeon should also note the patient's Fitzpatrick skin type, which affects the skin's response to these procedures. The Fitzpatrick scale classifies skin into 6 types according to skin color (before sun exposure) and the reaction of the skin to sun exposure. The higher the number is, the greater the amount of skin pigment. Thus, Fitzpatrick type I refers to fair skin with minimal pigmentation, and type VI represents skin with marked pigmentation.

In addition, the surgeon should assess eyelid skin and fat along with eyelid margin position relative to the pupil and cornea, presence or absence of horizontal lower eyelid laxity, midface and chin position, presence of jowling, and accumulation of subcutaneous

fat in the neck, noting any nasal deformities (tip descent or broadening) or thinning of the lips. The surgeon may find a side view of the neck to be particularly helpful in determining the extent of aging. Preoperative photographs should be available in the operating room.

Nonsurgical Facial Rejuvenation

Nonsurgical facial rejuvenation techniques such as laser resurfacing, soft-tissue dermal fillers, neurotoxin injection, chemical peels, and microdermabrasion are used to treat involutional and actinic facial skin changes. These superficial procedures may precede or be combined with surgical procedures that reposition deeper structures. It is important to remember that the upper eyelid appearance is inextricably linked to the position of the eyebrow. Similarly, the lower eyelid appearance is linked to the position of the midface, as well as the lower face and neck. Subunits of the facial cosmetic superstructure should not be viewed or manipulated individually but must be addressed in the context of the entire face and neck.

Chemical Peels

Chemical skin resurfacing has been used since the 1800s to treat melasma and other dermatologic disorders of pigmentation. Chemical peels are categorized based on the depth of action of treatment. Superficial peels, such as glycolic acid, a type of alpha-hydroxy acid (AHA), work by exfoliating epidermal layers but stop at the basal layer. Trichloroacetic acid (TCA) is a medium-depth peeling agent that destroys the cells in the epidermis and dermis, depending on its concentration. New keratinocytes are expected to replace the abnormal cells and stimulate new collagen production. Both superficial and medium-depth peels are used for the treatment of pigmentary disorders as well as signs of photoaging, including fine lines and wrinkles. Deep chemical peels ablate the epidermis and dermis and are generally accomplished with high-concentration TCA (>50%) and phenol for pigmentary disorders and scars. It is important that the physician consider the Fitzpatrick skin type when choosing the depth of peeling, because skin types with higher numbers may run the risk of further hyperpigmentation with deeper peels.

Laser Skin Resurfacing

Laser skin resurfacing is designed to reduce wrinkles and enhance the texture and appearance of the facial and periorbital skin. A variety of lasers have been developed to perform laser resurfacing; superpulsed or ultrapulsed carbon dioxide (CO_2) and erbium:yttrium-aluminum-garnet (Er:YAG) lasers are the most widely used. Traditional ablative lasers remove the entire epidermis, resulting in longer postprocedural erythema, whereas fractional ablative lasers remove less than 60% of the epidermis by creating microablated columns (MACs) with interspersed areas of untouched epithelium that promote faster re-epithelialization and decreased postprocedural erythema. Accordingly, the development of superpulsed CO_2 lasers has allowed ablative skin resurfacing without excessive thermal damage. Superpulsed and ultrapulsed CO_2 lasers deliver small pulses of high-energy light

to the skin; pauses between these pulses allow cooling of the tissues in the treated area, minimizing the risk of thermal damage. The Er:YAG laser has a nearly pure ablative effect on collagen- and water-containing tissues, with a much smaller zone of thermal injury and much less heat transfer into tissue than the CO_2 lasers.

Laser resurfacing is a useful adjunct to lower blepharoplasty, face-lifts, and neck-lifts. The skin-shrinking, collagen-tightening effect of laser skin resurfacing often allows the surgeon to avoid making an external incision and removing skin. It can also be useful in the management of scars and festoons and facilitate postoperative healing.

Patient selection is vital for successful laser skin resurfacing. Patients with a fair complexion and generally healthy, well-hydrated skin are ideal candidates. Patients with greater degrees of skin pigmentation can be safely treated, but care and caution are needed. The darker the skin pigmentation is, the greater the risk of postoperative inflammatory hyperpigmentation. Contraindications include inappropriate, unrealistic expectations, the presence of collagen vascular disease such as active systemic lupus erythematosus, and significant uncorrected lower eyelid laxity.

Herpes simplex virus infection after laser resurfacing may lead to scarring; therefore, most surgeons prophylactically treat patients with suppressing doses of antiviral agents against outbreaks of herpes simplex virus. Other complications associated with laser skin resurfacing include a variety of ophthalmic problems such as lagophthalmos, exposure keratitis, corneal injury, ectropion, and lower eyelid retraction.

A desire to improve superficial skin characteristics and facial wrinkling without the prolonged period of healing and erythema seen with ablative laser skin resurfacing has led to the development of devices that use fractionated lasers, intense pulsed light, ultrasound, or radiofrequency to deliver energy to the skin. These modalities can potentially even skin tone, remove cutaneous dyschromias or fine wrinkles, and even lift and smooth facial tissues. Each of these devices has its own risks and limitations but offers some improvement in aspects of facial aging, with fewer risks and shorter recovery times than with ablative laser skin resurfacing.

Cosmetic Uses of Botulinum Toxin

The use of botulinum toxin in patients with benign essential blepharospasm and hemifacial spasm (HFS) led to the observation that botulinum toxin reduces or eliminates some facial wrinkles. The first neurotoxin available for aesthetic indications was onabotulinumtoxinA. The FDA approved it to temporarily reduce wrinkles in the glabellar area and forehead and to diminish the appearance of the lateral canthal lines (crow's-feet). AbobotulinumtoxinA, the second neurotoxin to become available in the United States, has also been approved for the treatment of wrinkles in the glabellar area. IncobotulinumtoxinA has been approved for both cosmetic and medical applications, including blepharospasm; it is free of complexing protein, theoretically decreasing risk of sensitization, and can be stored at room temperature. A number of non–FDA-approved botulinum toxin products are available worldwide; however, US physicians should recognize the significant risks associated with using a non–FDA-approved substance for injection. Also, unit potency differs among these products, requiring that careful dosing adjustments be made.

Apart from the glabella, the areas most amenable to neuromodulation are the forehead, lateral canthal lines, perioral rhytids, and platysmal bands. The amount of botulinum toxin required and the location of injections vary significantly among patients and should be individualized.

The eyebrow can be chemically lifted when botulinum toxin is injected into the depressors of the eyebrow. The corners of the mouth can be elevated with injection into the depressor anguli oris muscle. The onset of action, peak effect, duration of effect, and complications of botulinum toxin for cosmetic purposes are the same as those noted for botulinum toxin as therapy for benign essential blepharospasm in Chapter 12 of this volume.

Soft-Tissue Dermal Fillers

Many formulations of fillers are available for nonsurgical facial rejuvenation. Hyaluronic acid fillers do not require allergy testing and have been approved by the FDA for the treatment of facial wrinkles or folds such as the nasolabial folds (Fig 13-2), for lip augmentation, and to correct age-related volume loss in the cheek area. Off-label usage of hyaluronic acid fillers for the periocular region (Fig 13-3) has been described extensively in the literature, but these fillers must be used with care. Complications from intravascular injection, including regional soft-tissue necrosis and central retinal artery occlusion, have been reported. In central retinal artery occlusion, retrograde embolization follows inadvertent high-pressure injection into an artery (see Chapter 9, Fig 9-8). The nasal dorsum and glabella are two of the most vulnerable locations for filler injections that lead to vision loss. In cases of local or regional soft-tissue necrosis from filler injection, some physicians inject hyaluronidase and administer hyperbaric oxygen. There are no definitive therapies for reversal of vision loss. Nonhyaluronic acid fillers, including those comprised of calcium hydroxylapatite and poly-L-lactic acid, are sometimes employed to promote collagen production and volume augmentation, but these also carry risk of intravascular complications and nodule formation; for these reasons and because there is no agent that reverses the effects of these fillers, proper training and experience are necessary for their administration.

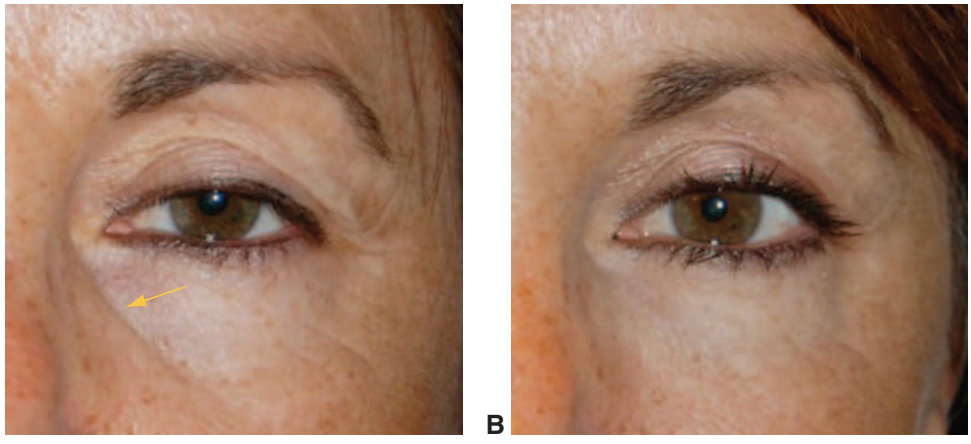

Figure 13-3 The tear trough before *(arrow)* **(A)** and after **(B)** injection of a hyaluronic acid filler to improve the contour of the lower eyelid. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Autologous Fat Grafting

With the advent of liposuction and refinements in the technique, this procedure has evolved into a safe and predictable means of restoring facial volume. Its biocompatibility makes fat a suitable filler. Any area treatable with the commercial dermal fillers discussed in the previous section is potentially treatable with fat grafting. These areas include, but are not limited to, the periocular area, temples, forehead, brow, cheeks, midface, lips, nasolabial fold, jawline, submental crease, and chin. As with commercial dermal filler injection, fat grafting carries the risk of intravascular injection. Additionally, fat grafts can exhibit variable growth, resorption, or palpability if injected too superficially.

Surgical Facial Rejuvenation

Facial and eyelid surgery should be approached with care. Adequate preoperative preparation includes properly informing the patient of the proposed benefits as well as the potential complications of the procedure. Significant complications—including facial nerve paralysis, skin flap necrosis, and vision loss—are potential risks. It is important to identify patients with unrealistic expectations and help provide counseling and resources for redirection.

Rejuvenation of the aging face requires a multitude of techniques. Chemical peeling, laser resurfacing, dermabrasion, and liposculpting can enhance the results of surgery, or, at times, may be preferred to incisional surgery.

Lower Blepharoplasty

Satisfactory results after cosmetic lower eyelid surgery often require additional skin rejuvenation with skin removal, chemical peels, and/or laser resurfacing. In the preoperative discussion, the surgeon should clearly describe reasonable expectations for, as well as

the risks of, the procedure. Patients should understand that aggressive resection of lower eyelid skin and fat may lead to eyelid retraction, ectropion, or a sunken, aged periorbital appearance. Preoperative examination for lower blepharoplasty includes testing of the elasticity (snapback test) and distractibility of the lower eyelid; the surgeon should be alert to the possible need for horizontal tightening of the lower eyelids along with the blepharoplasty. Furthermore, prominent orbital rims, malar hypoplasia, relative exophthalmos, and the presence of festoons should be notated and discussed with the patient.

Lower blepharoplasty can be accomplished through a transconjunctival incision or a transcutaneous, infraciliary incision (Video 13-1). The *transconjunctival incision* offers a lower rate of postoperative eyelid retraction and absence of an external postoperative scar (Fig 13-4). The preoperative evaluation defines the location and extent of lower eyelid fat prolapse and thus determines the boundaries of surgical excision. The surgeon should

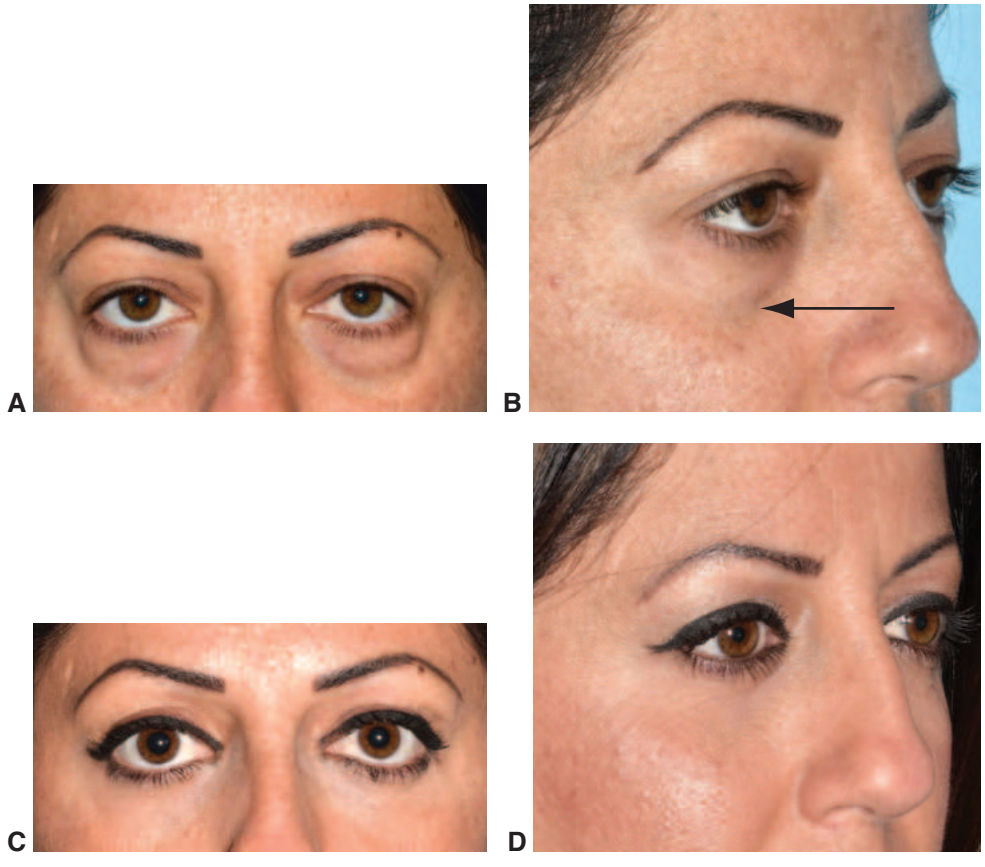

Figure 13-4 Transconjunctival lower eyelid blepharoplasty with orbital fat redraping. Images taken before surgery demonstrate the double convexity deformity with orbital fat prolapse **(A)** and unmasking of the inferior orbital rim *(arrow)* **(B). C, D,** Images taken after surgery show resolution of the double-convexity deformity and a smooth eyelid and cheek junction. *(Courtesy of Bobby S. Korn, MD, PhD.)*

be aware of the location of the inferior oblique muscle, which is between the medial and central fat pads. As in the upper eyelid, the medial fat pad of the lower eyelid is less yellow than the lateral fat pads. The central fat compartment is separated from the lateral fat compartment by the arcuate expansion of the inferior oblique muscle; removal or incision of this arcuate expansion may improve access to the lateral fat pad. The surgeon can remove or reposition the fat. Horizontal tightening or resuspension (see Chapter 12, Fig 12-2) is often performed with lower blepharoplasty.

VIDEO 13-1 Lower blepharoplasty.

After structural alteration of the lower eyelid (eg, fat removal, fat transposition, midface resuspension, horizontal eyelid tightening), skin removal can be performed. When skin resection is necessary, an *infraciliary incision* is used to remove only the skin while preserving the underlying pretarsal orbicularis muscle. It is important to note that aggressive skin removal during lower blepharoplasty increases the risk of lower eyelid contour abnormalities, retraction, and ectropion. This risk can be minimized with conservative skin removal and lower eyelid tightening.

Patients should be observed for orbital hemorrhage and managed as quickly as possible (see Chapter 6). Diplopia, another serious complication of blepharoplasty, may result from injury to the inferior oblique, inferior rectus, or superior oblique muscle. The inferior oblique muscle originates in the anterior orbital floor lateral to the lacrimal sac and travels posterolaterally within the lower eyelid retractors. It separates the central and medial fat pads of the lower eyelid and, thus, may be injured during removal of fat or inadvertently sutured to the inferior orbital rim during fat redraping procedures in lower blepharoplasty. In upper blepharoplasty, the trochlea of the superior oblique muscle may be damaged by deep dissection of orbital fat in the superonasal quadrant of the upper eyelid.

Forehead Rejuvenation

Endoscopic techniques allow the surgeon to raise the brow and rejuvenate the forehead *(foreheadplasty)* through small incisions approximately 1 cm (though incisions may vary) behind the hairline (Fig 13-5). Dissection is accomplished with an endoscopic periosteal elevator and blunt dissectors. Key steps are the creation of the incisions, creation of an optical cavity, periosteal release at the orbital rim, and fixation of the elevated flap. The forehead can be fixated using a drilled bone tunnel through the calvarium, resorbable anchors, or fixation screws. The advantages of the endoscopic technique are smaller incisions hidden within the hair, elevation of a lower hairline (short forehead), customized lifting of specific segments of the brow, and faster recovery (relative to pretrichial browlift) (Fig 13-6). The disadvantages include the need for endoscopic equipment, risk of damage to the facial nerve, possibility of alopecia around scalp incisions, and skin changes related to the fixation technique used.

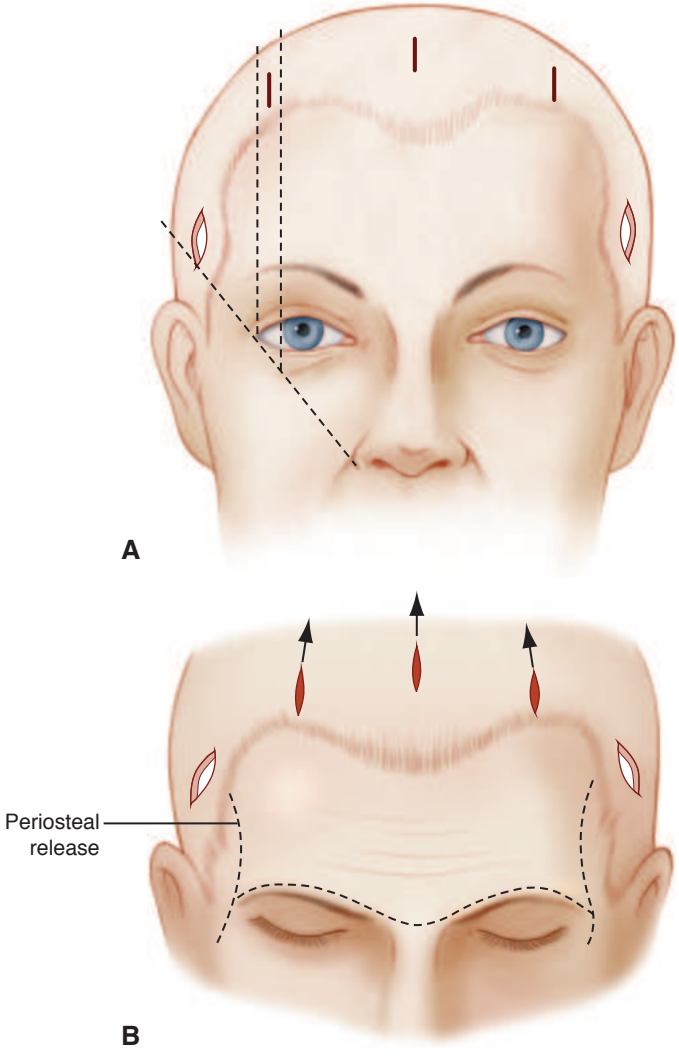

Figure 13-5 Endoscopic forehead-lift. **A,** Location of incisions. **B,** After periosteal release, the scalp is retracted posteriorly and fixated in the 2 paracentral incisions with a fixation screw, drilled bone tunnel, or absorbable implant. *(Illustration by Christine Gralapp.)*

The pretrichial approach is used in patients who have a high hairline. Access is gained through a hairline incision (Fig 13-7) instead of the small skin incisions used with the endoscopic approach. Dissection is performed in the subcutaneous layer. An appropriate amount of forehead skin is resected, and the underlying frontalis and galea are plicated with a subsequent layered closure. The advantages of the pretrichial technique are powerful lifting of the brow without elevation of the hairline and that there is no need for endoscopic equipment. The disadvantages are a relatively high incidence of postoperative sensory paresthesias and a visible scar line.

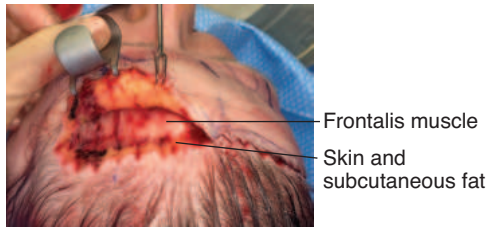

Figure 13-7 Pretrichial incision with beveled, undulating incision for forehead and brow elevation. The plane of dissection is the subcutaneous layer. *(Courtesy of Catherine Y. Liu, MD, PhD.)*

Midface Rejuvenation

The entire midface should be evaluated in a patient presenting for lower eyelid blepharoplasty. With age, cheek tissue descends and orbital fat herniates, creating a double-convexity deformity (see Fig 13-4 A, B). Attenuation of the orbitomalar, masseteric cutaneous, and zygomatic ligaments are the pathologic changes that occur with midfacial ptosis. Elevation of the suborbicularis oculi fat (SOOF) and midface, combined with conservative fat removal or redistribution, can restore the youthful anterior projection of the midface. This can also be achieved with dermal filler in more subtle cases and with a surgical cheek implant in cases of significant cheek descent.

Midface elevation can be achieved through a preperiosteal or subperiosteal approach. The preperiosteal plane can be accessed through the lower eyelid, with or without release of the lateral canthal tendon, or by using the temporal scalp incision employed in an endoscopic forehead-lift. The subperiosteal midface can also be accessed through these incisions or through a superior gingival sulcus incision (Fig 13-8). The goal of these procedures is to provide release of the midface tissues, followed by elevation and resuspension. Midface elevation is commonly combined with additional procedures such as a brow-lift, lower face-lift, or volume augmentation.

Lower Face and Neck Rejuvenation

During preoperative evaluation, the face and neck should be considered as a single cosmetic unit. Correction of the cosmetic subunits of the upper face and midface without addressing the lower face and neck can create an unbalanced appearance. At the very least, these concerns must be discussed with the patient preoperatively, along with surgical options.

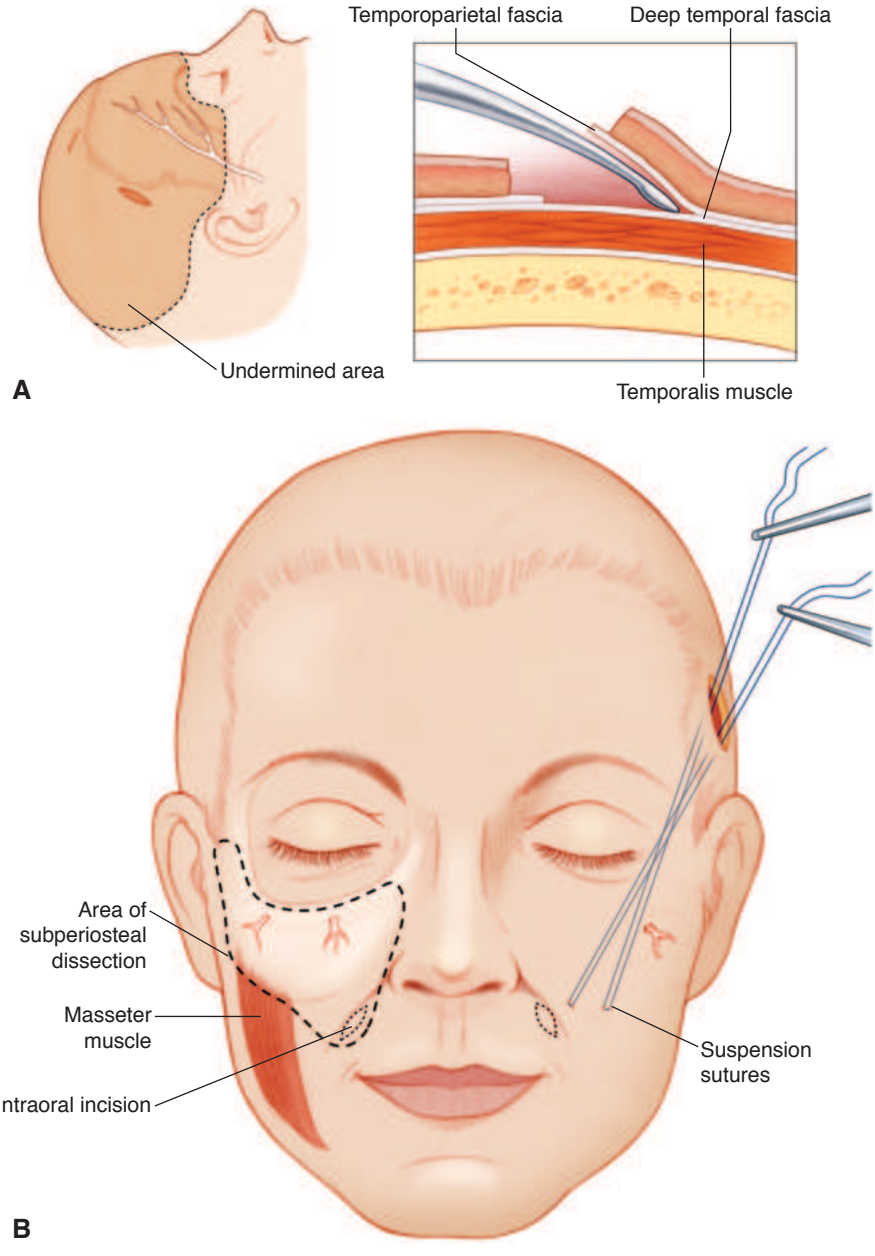

Figure 13-8 Endoscopic approach to subperiosteal midface-lift. **A,** Undermining between the temporoparietal fascia and the deep temporal fascia to approach the anterior face of the maxilla. **B,** Midface subperiosteal dissection and suture fixation. *(Illustration by Christine Gralapp.)*

Rhytidectomy

The most commonly performed procedures include the vintage (subcutaneous) rhytidectomy, the rhytidectomy with superficial elevation and refixation of the superficial musculoaponeurotic system (SMAS) (Fig 13-9), and the deep-plane rhytidectomy. Rhytidectomies

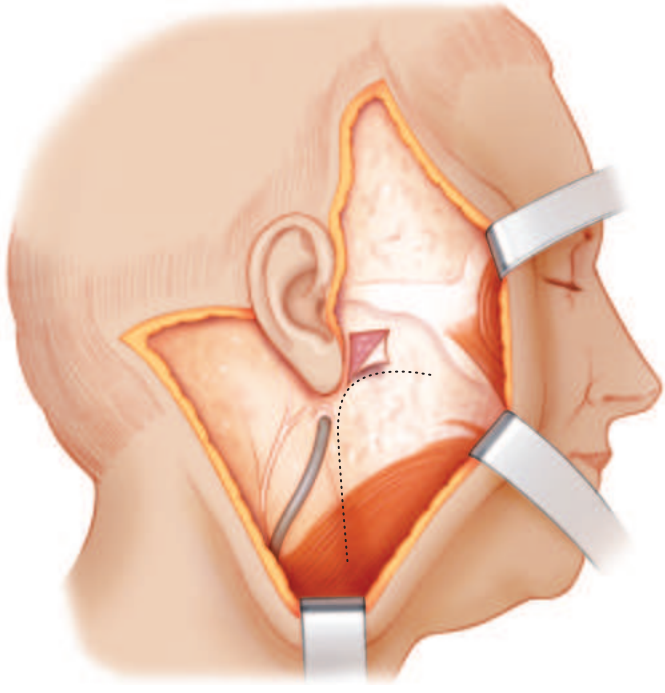

Figure 13-9 The common goal of rhytidectomy procedures is modification of the superficial musculoaponeurotic system (SMAS), which translates to changes in the overlying anatomy. After release of the SMAS *(dotted line),* the SMAS is pulled laterally and superiorly for elevation of the jowls and lower face. *(Illustration by Christine Gralapp.)*

typically include surgical management of the jowls and neck, including liposuction with or without platysmaplasty (Fig 13-10). The 3 rhytidectomy procedures mentioned differ mainly in the location and extent of dissection. Although the more superficial procedures are less likely to cause facial nerve damage, they may produce shorter-lasting results. The more extensive procedures have greater risks (eg, facial nerve injury), but the likelihood that they will produce dramatic, longer-lasting improvement is also greater.

Complications of rhytidectomy are directly related to the extent of subcutaneous undermining; they include hematoma, seroma, skin necrosis, hair loss, paresthesias, motor deficits, incisional scarring, asymmetry, earlobe distraction (pixie-ear deformity), and contour irregularities. Hematoma is the leading surgical face-lift complication, but patient dissatisfaction may be the most common postoperative issue.

Neck liposuction

Neck liposuction enhances the neckline and is often performed in conjunction with other cosmetic procedures. Stab incisions, or *adits,* are made just posterior to the earlobe on each side and along the submental incision line; if liposuction is performed as a standalone procedure, they are made just anterior to the submental crease. Small liposuction cannulas are used for fat removal. A layer of fat is left on the dermis, and the liposuction cannula openings are always oriented away from the dermis to avoid injury to the

Figure 13-10 Photographs of a patient who underwent rhytidectomy with submental liposuction. **A,** Images taken prior to surgery. **B,** Images taken after the procedure. Note the improvement in the jowls and sharpening of the cervicomental angle. *(Courtesy of Robert G. Fante, MD.)*

vascular plexus deep to the dermis. In addition to abnormalities in skin quality, damage in this area can lead to unsightly scarring of the dermis of the underlying neck musculature. The adits are left open or sutured, and a compression bandage is worn for 1 week after the procedure.

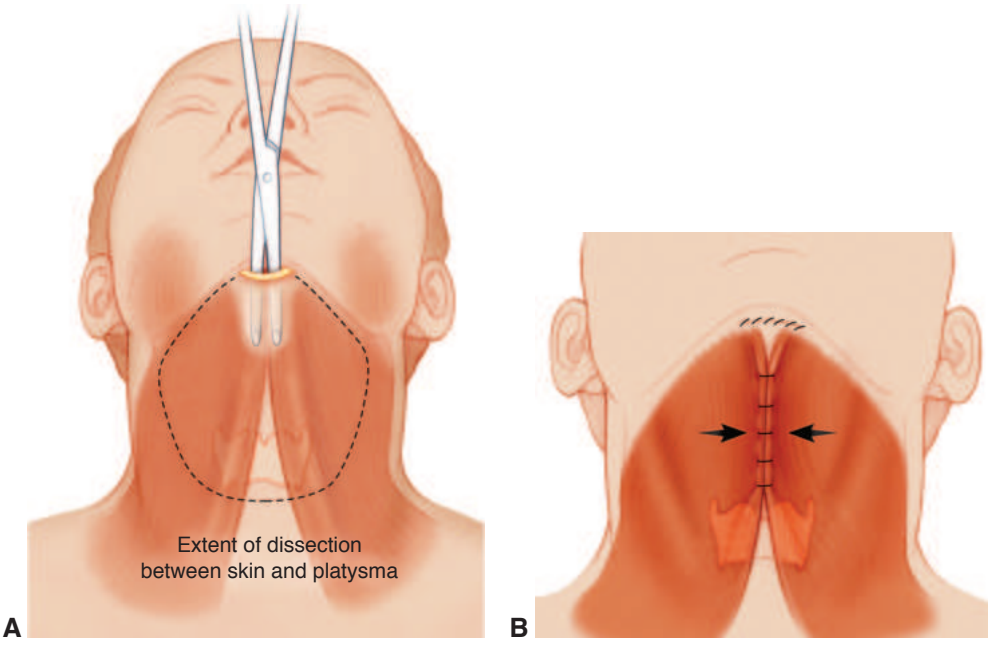

Figure 13-11 Cervicoplasty. **A,** Undermining of the skin. **B,** Platysmaplasty. *(Illustrations by Christine Gralapp.)*

Platysmaplasty

Platysmaplasty is performed to correct platysmal bands and is typically done in conjunction with a lower face-lift. A subcutaneous dissection is carried out in the preplatysmal plane centrally under the chin to the level of the thyroid cartilage (Fig 13-11A). Lateral platysmal undermining and suspension may be performed as part of a rhytidectomy. Midline platysma resection and reconstruction (Fig 13-11B) are performed if midline neck support is needed. A drain and a light compression dressing are placed. Postoperatively, the cervicomental angle is more acute, yielding a more youthful look.

PART III
Lacrimal System

CHAPTER 14

Development, Anatomy, and Physiology of the Lacrimal Secretory and Drainage Systems

This chapter includes a related video. Go to www.aao.org/bcscvideo_section07 or scan the QR code in the text to access this content.

Highlights

- The lacrimal secretory and drainage systems are derived from the ectodermal germ layer.
- Congenital nasolacrimal duct obstruction (NLDO) may not be apparent until lacrimal secretory function commences at approximately 6 weeks of age.
- Biopsy of the lacrimal gland is preferentially performed on the orbital lobe to avoid damage to the secretory ducts, which provide tears to the ocular surface via the superior cul-de-sac.
- The lacrimal pump mechanism actively drains tears during the blink cycle.

See Chapters 1 and 4 in BCSC Section 2, *Fundamentals and Principles of Ophthalmology,* for additional discussion, including illustrations, of some of the topics covered in this chapter.

Development

Secretory System

The lacrimal gland develops from multiple solid ectodermal buds in the anterior superolateral orbit. These buds branch, canalize, and form ducts and alveoli. The lacrimal glands are small and do not function fully until approximately 6 weeks after birth. Thus, newborn infants do not produce tears when they cry.

Drainage System

By the end of the fifth week of gestation, the nasolacrimal groove forms as a furrow that lies between the nasal and maxillary prominences. In the floor of this groove, the nasolacrimal

duct (NLD) develops from a linear thickening of the ectoderm. A solid cord then separates from adjacent ectoderm and sinks into the mesenchyme. The cord canalizes, forming the NLD and the lacrimal sac at its cranial end. The canalicular system is an outgrowth of the lacrimal sac. Caudally, the developing duct extends intranasally, exiting beneath the inferior meatus. The central tissue of this cord eventually undergoes apoptosis, forming a lumen. Canalization of the NLD is usually complete around the time of birth. A residual membrane obstructing the distal aspect of the duct at the valve of Hasner represents the most common cause of congenital NLDO; it is symptomatic in approximately 5% to 20% of infants at birth. Patency usually occurs spontaneously within the first few months of life. As noted earlier, since tear production does not normally occur until 6 weeks of age, excessive tearing may not be immediately obvious even if an obstruction exists.

Anatomy

Secretory System

The lacrimal gland is an exocrine gland located in the superolateral orbit within the lacrimal gland fossa. Embryologic development of the lateral horn of the levator aponeurosis indents the lacrimal gland, dividing it into orbital and palpebral lobes (see Chapter 1, Fig 1-7) as it traverses laterally to insert on the lateral orbital tubercle (Whitnall tubercle). The superior transverse ligament (Whitnall ligament) forms septa through the stroma of the gland, with some fibers also projecting onto the lateral orbital wall several millimeters above the lateral orbital tubercle.

Between 8 and 12 major lacrimal ducts empty into the superior cul-de-sac, which is located approximately 5 mm above the lateral tarsal border, after passing posterior to the levator aponeurosis and through the Müller muscle and conjunctiva. Because the lacrimal excretory ducts traverse the palpebral portion of the gland, removal of the palpebral lobe may reduce secretion from the entire gland. Therefore, biopsy of the lacrimal gland is preferentially performed on the orbital lobe.

Ocular surface irritation activates tear production from the lacrimal gland. The ophthalmic branch of the trigeminal nerve, cranial nerve (CN) V, provides the sensory *(afferent)* pathway of the reflex tear arc. The *efferent* pathway is more complicated. Parasympathetic fibers that originate in the superior salivatory nucleus of the pons exit the brainstem with the facial nerve, CN VII (Fig 14-1). Lacrimal fibers leave CN VII as the greater superficial petrosal nerve and pass into the sphenopalatine ganglion. From there, they are believed to enter the lacrimal gland via the superior branch of the zygomatic nerve, through an anastomosis between the zygomaticotemporal nerve and the lacrimal nerve. It is unclear whether this anastomosis is uniformly present. The role of the sympathetic nervous system in lacrimation is not well understood.

The *accessory glands of Krause* and *Wolfring* are exocrine glands located deep within the superior fornix and just above the superior border of the tarsus, respectively. Aqueous

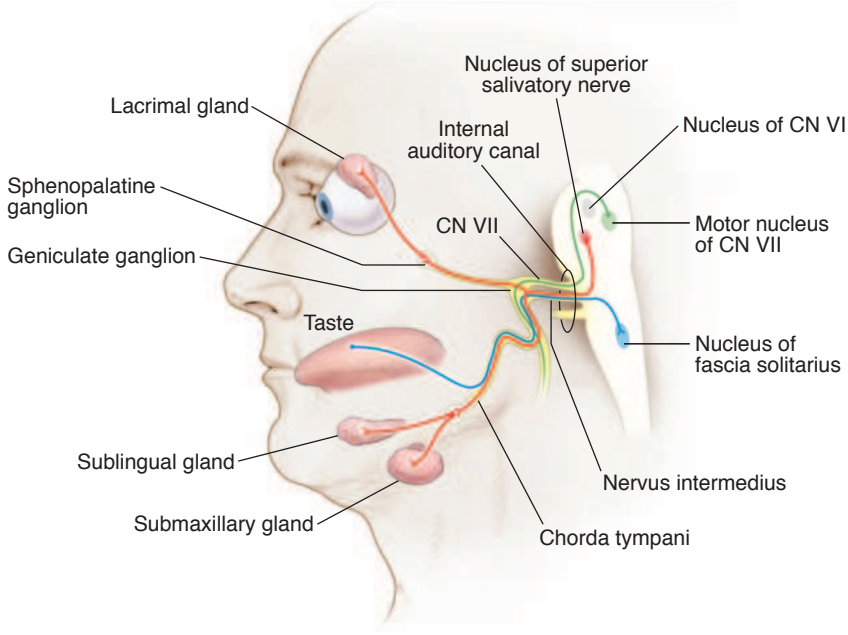

Figure 14-1 Nonmotor pathways of cranial nerve VII, including the efferent pathway to the lacrimal gland. *(Illustration by Christine Gralapp.)*

lacrimal secretion has traditionally been divided into basal secretion and reflex secretion. Previously, it was thought that the accessory glands predominate in basal tear secretion, and that the lacrimal gland was responsible for reflex tearing. It is now believed that all glands respond as a unit.

The tear film is a uniform gel comprised of proteins and fluids secreted by the lacrimal gland and mucus from conjunctival goblet cells. The tear film creates a smooth optical surface, and the air–tear film interface is the primary refractive element of the eye. In addition, the tear film contains a host of proteins that regulate the ocular flora. See BCSC Section 2, *Fundamentals and Principles of Ophthalmology,* and BCSC Section 8, *External Disease and Cornea,* for more detailed discussions of the tear film.

Drainage System

Tears enter the lacrimal drainage system through *puncta* located medially on the margin of the upper and lower eyelids (Fig 14-2). Each punctum appears at the apex of a fleshy papilla that protrudes slightly above the eyelid margin, and is slightly inverted and apposed to the globe, to rest within the tear lake. The inferior punctum is slightly more lateral than the superior punctum. The puncta are approximately 0.3 mm in diameter and lead to a vertical segment of the *lacrimal canaliculi* known as the ampulla. The canaliculi then turn 90°, continuing 8–10 mm medially to join at the common canaliculus and connect with the *lacrimal sac* through the valve of Rosenmüller. Less frequently, the

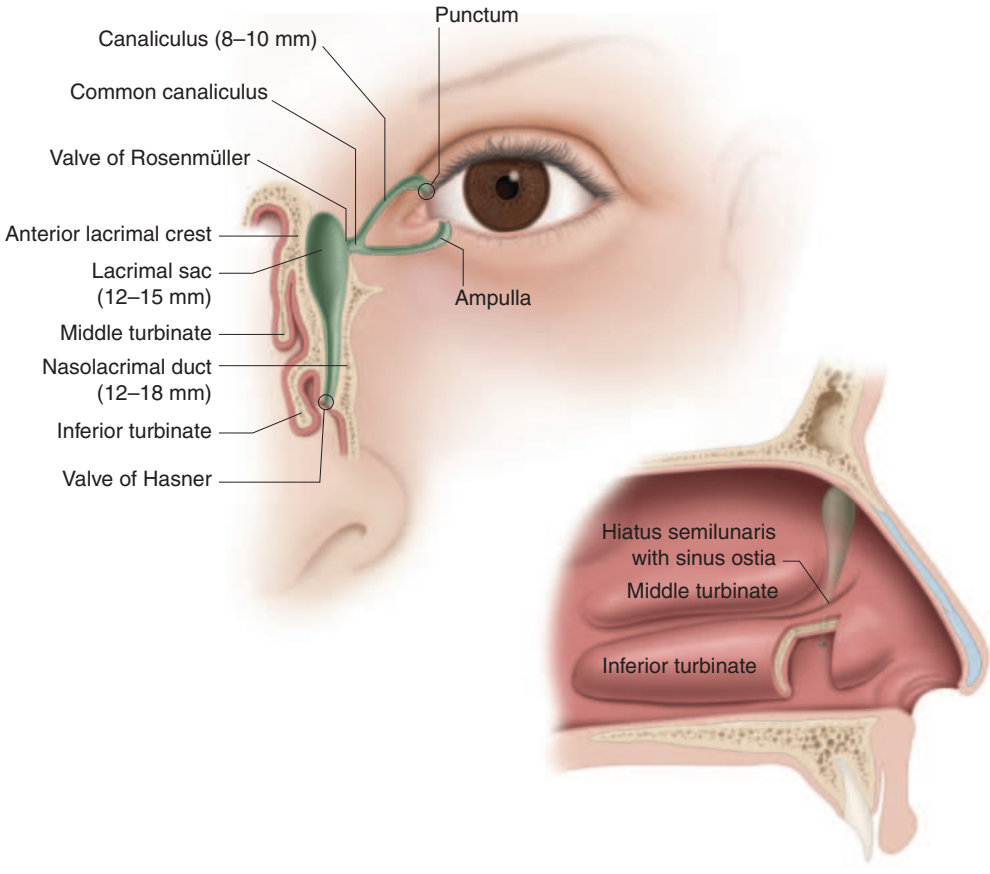

Figure 14-2 Normal anatomy of the lacrimal drainage system. The measurements provided are for adults. *(Illustration by Mark Miller.)*

canaliculi connect directly to the lacrimal sac without a common portion. The canaliculi are lined with nonkeratinized, non–mucin-producing stratified squamous epithelium. This epithelium transitions to a stratified columnar epithelium in the distal portion of the canaliculi, which continues through the lacrimal sac and NLD. For reasons that are not completely understood, the Na^+/I (sodium/iodide) symporter (NIS) is present in this epithelium, which can lead to stenosis during treatment with high-dose radioactive iodine for thyroid cancer.

The *valve of Rosenmüller* (see Fig 14-2) is a fold of mucosal tissue that has traditionally been described as the structure that prevents reflux of tears from the sac into the canaliculi. However, studies suggest that the common canaliculus consistently bends from posterior to anterior behind the medial canthal tendon before entering the lacrimal sac at an acute angle. This bend, in conjunction with the fold of mucosa, may play a role in blocking reflux.

The lacrimal sac lies within a bony fossa bordered by the anterior and posterior lacrimal crests (see BCSC Section 2, *Fundamentals and Principles of Ophthalmology,* Fig 1-1,

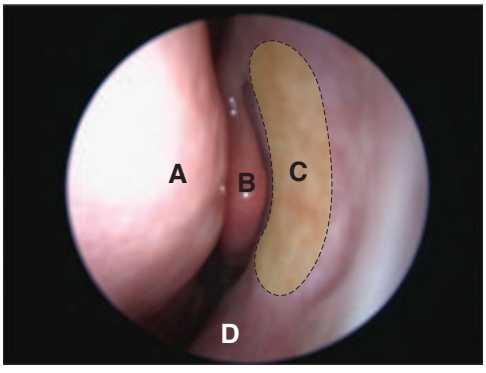

Figure 14-3 Endoscopic intranasal anatomy *(left side)*. Note the septum **(A),** middle turbinate **(B),** and area of mucosa and bone to be removed to expose the lacrimal sac **(C).** The superior portion of the inferior turbinate is visible at the bottom **(D).** *(Courtesy of Eric A. Steele, MD.)*

for a photograph of this fossa). The medial canthal tendon is a complex structure composed of superior, anterior, and posterior crura that envelop the superior aspect of the lacrimal sac. The superficial head of the tendon attaches to the anterior lacrimal crest, and the deep head (with the Horner muscle) attaches to the posterior lacrimal crest. The medial wall of the fossa is composed of the lacrimal bone posteriorly and the frontal process of the maxillary bone anteriorly. Medial to the fossa is the middle meatus of the nose, sometimes with intervening ethmoid air cells. From an intranasal view, the location of the lacrimal sac corresponds to the lateral nasal wall just anterior to the middle turbinate (Fig 14-3). The fundus of the sac, which is more fibrous than the rest of the sac, extends several millimeters above the medial canthal tendon. Inferiorly, the lacrimal sac transitions into the NLD. When performing an external dacryocystorhinostomy, the surgeon should be mindful of the angular artery and vein that lie medial to the medial canthal angle and thus avoid unnecessary bleeding. Additionally, careful blunt dissection will preserve distal fibers of the zygomatic and buccal branches of the facial nerve and avoid temporary postoperative lagophthalmos.

In adults, the NLD measures 12–18 mm in length. The intraosseous portion of the duct is typically 12 mm long, and the meatal duct extends 5–6 mm inferior to the bony ostium. The NLD travels through bone within the nasolacrimal canal, which initially curves in an inferior and slightly lateral and posterior direction from the lacrimal sac. The NLD opens into the nose through an ostium under the inferior turbinate (the inferior meatus), which is usually partially covered by a mucosal fold (the valve of Hasner; see Fig 14-2). The mucosal ostium in adults is typically located 30–35 mm from the external naris.

Physiology

Evaporation accounts for approximately 10% of tear elimination. Most of the tear flow is actively pumped from the tear lake by the actions of the orbicularis oculi muscle. Blinking pushes tears first laterally and then nasally from the eyelid margin. When the eyelids open, negative pressure pulls the tears into the sac; when the eyelids close, the action of the orbicularis muscle creates positive pressure that forces those tears

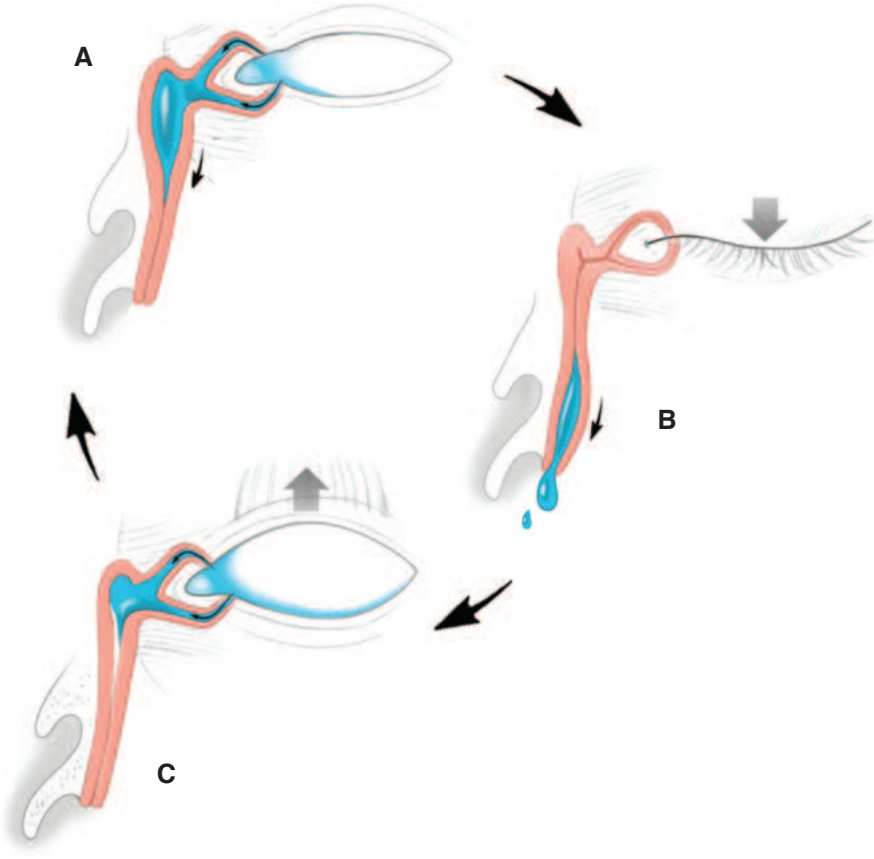

Figure 14-4 Lacrimal pump mechanism. **A,** In the relaxed state, the puncta lie in the tear lake, and the lacrimal sac is filled with tears. **B,** With eyelid closure, contraction of the pretarsal orbicularis closes the puncta and canaliculi. The preseptal orbicularis fibers, which insert onto the sac, also compress the sac, creating positive pressure that propels tears through the duct. **C,** With eyelid opening, the orbicularis relaxes, and the puncta and sac open, creating negative pressure that draws tears into the canaliculi and lacrimal sac. As the eyelids close, the cycle repeats. *(Original illustration by Christine Gralapp; revision based on an illustration by Cat N. Burkat, MD.)*

through the NLD (Fig 14-4, Video 14-1). A weakened blink interferes with the normal pumping mechanism and contributes to epiphora in patients with eyelid laxity or CN VII palsy.

CHAPTER 15

Abnormalities of the Lacrimal Secretory and Drainage Systems

This chapter includes related videos. Go to www.aao.org/bcscvideo_section07 or scan the QR codes in the text to access this content.

Highlights

- Congenital defects in the lacrimal system can be isolated or associated with other abnormalities.
- Management of congenital nasolacrimal duct obstruction includes conservative and surgical techniques.
- Tearing can be due to a wide variety of conditions.
- Canalicular injuries are commonly encountered with eyelid trauma.

Developmental Abnormalities

Lacrimal Secretory System

Congenital abnormalities of the lacrimal gland are rare. Hypoplasia and agenesis of the lacrimal gland can occur in isolation or in conjunction with congenital abnormalities of the salivary glands. Ectopic lacrimal gland tissue can be present within the orbit and eyelids. Seldomly, an aberrant lacrimal ductule (previously known as a *lacrimal gland fistula*) may exit externally through the central or lateral upper eyelid with an associated cluster of eyelashlike hairs or may exit through an orifice at the lateral canthus. Tears that egress through an aberrant ductule can mimic epiphora and can be successfully managed with simple excision of the tract.

Lacrimal Drainage System

Developmental abnormalities of the lacrimal drainage system include

- errors in the genesis of the proximal system
  - multiple puncta
  - lacrimal–cutaneous fistula

- incomplete patency
  - punctal or canalicular hypoplasia or aplasia
  - nasolacrimal duct obstruction (NLDO)

Duplication

Multiple puncta and additional canaliculi typically occur on the eyelid margin and are often asymptomatic and require no treatment (Fig 15-1). Lacrimal–cutaneous fistula is an uncommon tract that exits through the skin, typically infranasal to the medial canthus (Fig 15-2). This type of fistula is sometimes asymptomatic but may be associated with tears that appear on the skin. Approximately one-third of patients with lacrimal–cutaneous fistula also have an underlying NLDO; in these cases, chronic mucoid discharge from the affected nasolacrimal sac may be present.

In symptomatic patients, direct surgical excision of the epithelium-lined fistulous tract with primary suture closure is indicated. In patients with underlying NLDO and chronic dacryocystitis, lacrimal intubation or dacryocystorhinostomy may also be required. (See the subsection "Management" in the section Acquired Nasolacrimal Duct Obstruction later in this chapter.)

Aplasia and hypoplasia

Punctal hypoplasia and stenosis are encountered more frequently than true punctal aplasia (Fig 15-3). Management of punctal stenosis, membranes, and aplasia is discussed later in this chapter.

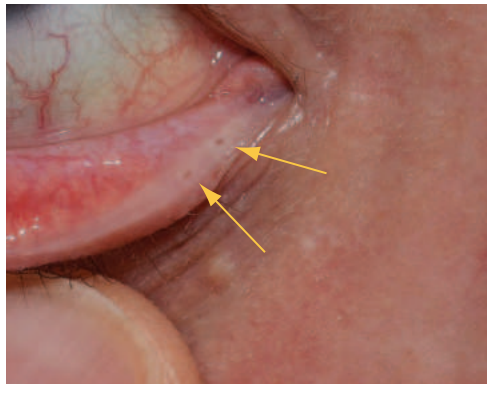

Figure 15-1 Multiple puncta *(arrows)* of the right lower eyelid. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Figure 15-2 Congenital lacrimal–cutaneous fistula *(arrow)*. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Figure 15-3 Congenital punctal aplasia. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Nasolacrimal duct obstruction

Congenital NLDO is typically due to failure of the duct to fully canalize but can be associated with more severe abnormalities. For example, major facial cleft deformities can pass through or occur adjacent to the nasolacrimal drainage pathways and can result in outflow disorders (see Chapter 3, Fig 3-3).

Treatment of lacrimal drainage obstruction differs according to the cause and location of the obstruction. Obstruction may involve the puncta, canaliculi, lacrimal sac, or nasolacrimal duct (NLD). Because the pathophysiology and management of congenital and acquired lacrimal drainage abnormalities differ, these disorders are addressed separately.

Congenital Lacrimal Drainage Obstruction

Evaluation

The evaluation of a patient with congenital tearing is typically straightforward. The patient's parent or guardian reports a history of tearing, mucopurulent discharge, or both, beginning shortly after birth. In rare cases, visible distention of the lacrimal sac is present, suggesting a congenital dacryocystocele. Otherwise, distinction should be made among the following:

- constant tearing with minimal mucopurulence, suggesting blockage of the upper system (puncta, canaliculi, and common canaliculus) caused by punctal or canalicular dysgenesis
- constant tearing with frequent mucopurulence and mattering of the eyelashes, suggesting complete obstruction of the NLD
- intermittent tearing with mucopurulence, suggesting intermittent obstruction of the NLD

Office examination includes inspection of the eyelid margins for proper apposition and patent puncta and evaluation for extrinsic causes of reflex hypersecretion, such as

- ocular surface irritation
- infectious conjunctivitis
- entropion
- epiblepharon
- trichiasis
- congenital glaucoma

Additional aspects of the examination include inspection of the medial canthal region to assess for a distended lacrimal sac (below the tendon), inflammation, or congenital defects such as an encephalocele (above the tendon). The single most important maneuver is application of digital pressure over the tear sac. If mucoid reflux is present, complete obstruction at the level of the NLD becomes the working diagnosis.

Punctal and Canalicular Agenesis and Dysgenesis

The medial eyelid margin is inspected for the presence of elevated lacrimal papillae and puncta. Close inspection may reveal a punctum with a membranous occlusion, which can usually be opened with a sharp probe. Temporary intubation may help prevent recurrence. If the punctum is truly absent, the surgeon may cut downward, through the eyelid margin, medial to the expected punctum location to try to identify the canaliculus. Occasionally, these maneuvers reveal a relatively mature canalicular system with a patent nasolacrimal sac and duct, in which case intubation may be performed. Symptomatic patients with complete absence of the puncta and the canalicular system require a conjunctivodacryocystorhinostomy (CDCR). This is performed when the patient is old enough to allow proper care of the glass (Jones) tube. (CDCR is discussed in the section Canalicular Obstruction later in this chapter.)

Congenital Nasolacrimal Duct Obstruction

Congenital obstruction of the lacrimal drainage system is usually caused by a membrane blocking the valve of Hasner at the nasal end of the NLD. Many newborns are born with imperforate NLDs, but most obstructions open spontaneously within the first few months of life. Such an obstruction becomes clinically evident in only 2%–6% of full-term infants at 3–4 weeks of age. Of these, one-third have bilateral involvement.

Management can be divided into nonsurgical and surgical options. Because approximately 90% of all symptomatic congenital NLDOs resolve in the first year of life, conservative options such as observation, digital compression over the lacrimal sac, and topical or even oral antibiotics, when necessary, are the initial recommendations. (See BCSC Section 6, *Pediatric Ophthalmology and Strabismus,* for information on management.)

When the obstruction fails to resolve with conservative measures, more invasive intervention may be required. Most often, this consists of probing of the NLD to rupture the membrane occluding the duct at the valve of Hasner (discussed in detail later in this chapter); most surgeons perform probing if symptoms persist at 1 year of age.

Probing can be performed in the office or in the operating room with general anesthesia. The choice is dependent on the experience of the surgeon. The benefits of in-office probing include avoidance of general anesthesia and cost-effectiveness, whereas the

disadvantages include discomfort of the awake infant. The advantages of surgery under general anesthesia include a more controlled environment and the ability to acquire more detailed information about the nature of the obstruction.

In some instances of congenital NLDO, dacryocystitis manifests as an acutely inflamed lacrimal sac with cellulitis of the overlying skin. Treatment with systemic antibiotics should be started promptly. Management of the pediatric patient is similar to that of the adult patient (discussed in detail later in this chapter). After resolution of the acute infectious process, elective probing is performed promptly to prevent recurrence of dacryocystitis.

Mohney BG, Sathiamoorthi S, Frank RD. Spontaneous resolution rates in congenital nasolacrimal duct obstruction managed with massage or topical antibiotics compared with observation alone. *Br J Ophthalmol.* 2022;106(9):1196–1199.

Congenital Dacryocystocele

A congenital dacryocystocele is a cystic dilatation of the lacrimal sac that occurs when there is a functional block above the sac (at the level of the valve of Rosenmüller) and an obstruction at the valve of Hasner, resulting in an accumulation of mucus secreted by lacrimal sac goblet cells. It may be present at birth or develop shortly thereafter and typically appears as a bluish mass below the medial canthus. Distension of the NLD component manifests as an intranasal cyst beneath the inferior turbinate, where it can be observed during nasal examination (Fig 15-4). Intranasal examination is thus a required component of the evaluation. Airway obstruction is possible, especially in the setting of bilateral involvement, as infants are obligate nasal breathers, and may present as difficulty feeding.

In most patients, dacryocystoceles demonstrate expansion inferior to the medial canthal tendon. Congenital swelling above the medial canthal tendon suggests alternative etiologies, such as a dermoid cyst or meningoencephalocele. Magnetic resonance imaging (MRI) is useful in evaluation of the patient for these more complex diagnoses.

Singh S, Ali MJ. Congenital Dacryocystocele: A Major Review. *Ophthalmic Plast Reconstr Surg.* 2019;35(4):309–317.

Probing and irrigation

The procedure begins with topical vasoconstriction of the nasal mucosa, usually with application of oxymetazoline hydrochloride. Punctal dilation is often necessary and is facilitated by first coating a size 00 Bowman lacrimal probe with ophthalmic ointment. The probe is initially inserted into the punctum, perpendicular to the eyelid margin, and then turned parallel to the eyelid margin as it is advanced medially along the canalicular system, toward the medial canthal tendon (Fig 15-5). Manual lateral traction of the eyelid with the opposite hand straightens the canaliculus, decreasing the risks of damage to the canalicular mucosa and creation of a false passage.

Resistance to passage of the probe—along with medial movement of the eyelid soft tissue ("soft stop"), which causes wrinkling of the overlying skin—may signify a canalicular obstruction. More commonly, resistance simply is due to a kink in the canaliculus created by bunching of the soft tissues in front of the probe tip. If kinking is encountered, the probe is withdrawn and reinserted while lateral horizontal traction is maintained (Fig 15-6). If

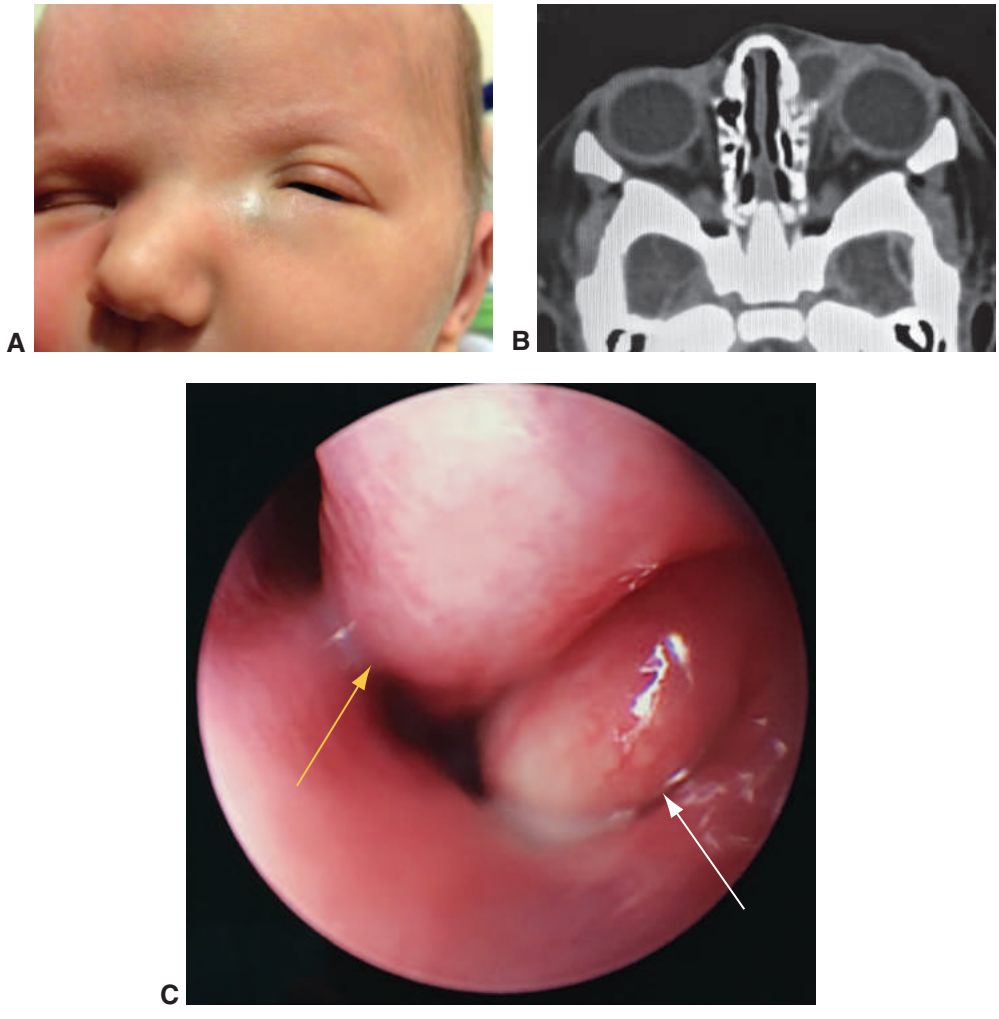

Figure 15-4 Congenital dacryocystocele. **A,** Left congenital dacryocystocele. **B,** Computed tomography (CT) scan of a congenital dacryocystocele. **C,** Endoscopic view of an associated intranasal cyst *(white arrow)* prolapsing under the inferior turbinate *(yellow arrow).* *(Parts A and B courtesy of Cat N. Burkat, MD ; part C courtesy of Pete Setabutr, MD.)*

the probe advances successfully through the common canalicular system and across the lacrimal sac, the medial wall of the lacrimal sac and adjacent lacrimal bone will be encountered, resulting in a tactile "hard stop."

The probe is then rotated 90° superiorly toward the brow until it lies adjacent to the supraorbital notch. Next, it is directed posteriorly and slightly laterally as it is advanced down the NLD. Creation of a false passage makes it difficult to redirect the probe back into the native lacrimal system. Therefore, if resistance is encountered and the surgeon is uncertain whether the probe is in the natural pathway, the probe is repositioned and passage attempted again. At some points of narrowing, particularly at the distal end of the NLD, gentle pressure may be necessary to push through the blockage. The probe tip can

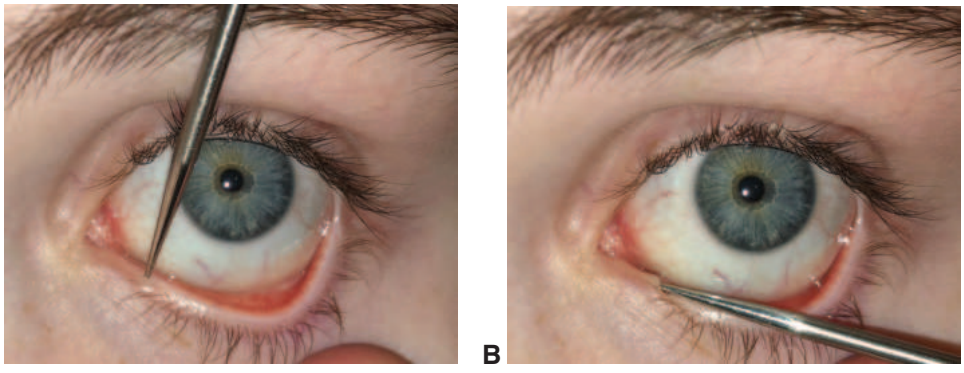

Figure 15-5 Punctal dilatation. **A,** Initial insertion of the punctal dilator is perpendicular to the eyelid margin. **B,** Next, with lateral countertraction on the eyelid, the dilator is directed horizontally into the canaliculus *(Courtesy of Eric A. Steele, MD.)*

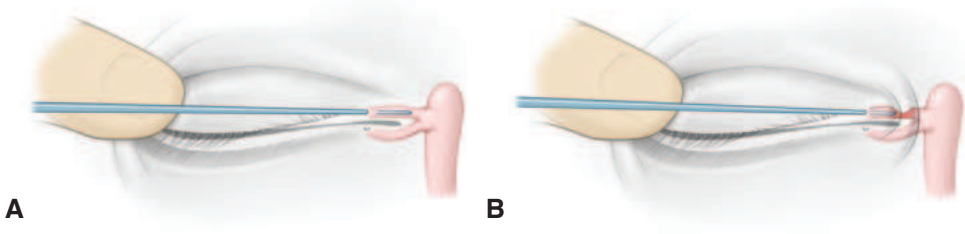

Figure 15-6 Proper technique for canalicular probing. **A,** A Bowman probe in the right upper horizontal canaliculus with lateral traction on the eyelid. **B,** When canalicular obstruction is present or when the probe is not in the correct position, resistance to passage of the probe ("soft stop") with wrinkling of the overlying skin is encountered. *(Illustration by Christine Gralapp.)*

be visualized along the lateral wall of the nose under the inferior turbinate, approximately 2 cm back from the nostril, with an endoscope or a nasal speculum with a fiber-optic headlight. Alternatively, patency of the duct can be confirmed by metal-on-metal contact with another probe inserted through the naris or by irrigation with saline mixed with fluorescein (Fig 15-7). The fluorescein can be retrieved from the inferior meatus and visualized with a transparent suction catheter. A single lacrimal probing successfully resolves congenital NLDO in 90% of patients who are 13 months or younger.

Intubation

Intubation with a lacrimal stent is indicated for children who have recurrent epiphora following nasolacrimal system probing and for older children in whom initial probing reveals significant stenosis or scarring. Intubation is also useful for the treatment of upper-system abnormalities such as canalicular stenosis, trauma, and agenesis of the puncta. Nasolacrimal intubation after failed probing has a reported success rate greater than 70%.

There are many intubation techniques and types of intubation sets. Figure 15-8 illustrates one of the more commonly used stents (ie, the Crawford stent). Keys to successful

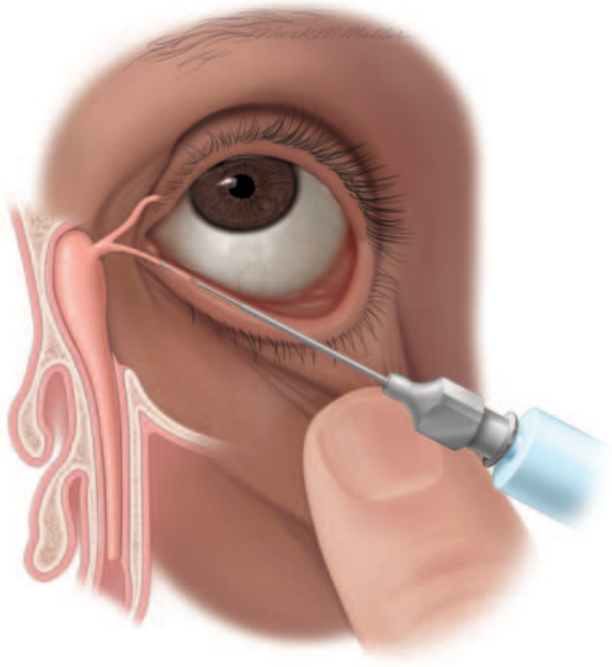

Figure 15-7 Irrigation of the nasolacrimal system. Dye is injected from the syringe, and patency of the system is confirmed by suctioning the dye from the inferior meatus of the nose. *(Illustration by Mark Miller.)*

intubation include shrinkage of the nasal mucosa with a topical vasoconstrictor and adequate lighting with a fiber-optic headlight. In more difficult cases, an endoscope can be used, and medialization of the inferior turbinate is sometimes performed. The lacrimal stent can be secured with a simple square knot, which allows removal of the stent through the canalicular system in a retrograde fashion. Alternatively, the lacrimal stent may be directly sutured to the lateral wall of the nose (without tension), or the limbs of the stent can be secured by passing them through either a silicone band or a sponge in the inferior meatus of the nose.

Another option is a self-retaining bicanalicular lacrimal stent that comes preloaded with a rigid inserter and does not require intranasal retrieval or fixation (Fig 15-9A). Alternatively, a monocanalicular stent is useful for patients with only one patent canaliculus (Fig 15-9B). This type of stent is passed through a single punctum to the nasal cavity, where the end of the stent is allowed to rest loosely in the nose. The proximal end has a punctal plug and is self-secured at the punctum.

Balloon dacryoplasty

Balloon catheter dilation of the nasolacrimal canal has been used successfully in patients with congenital nasolacrimal obstruction. A collapsed balloon catheter is placed in a manner similar to probing and is inflated inside the duct. The role of this modality

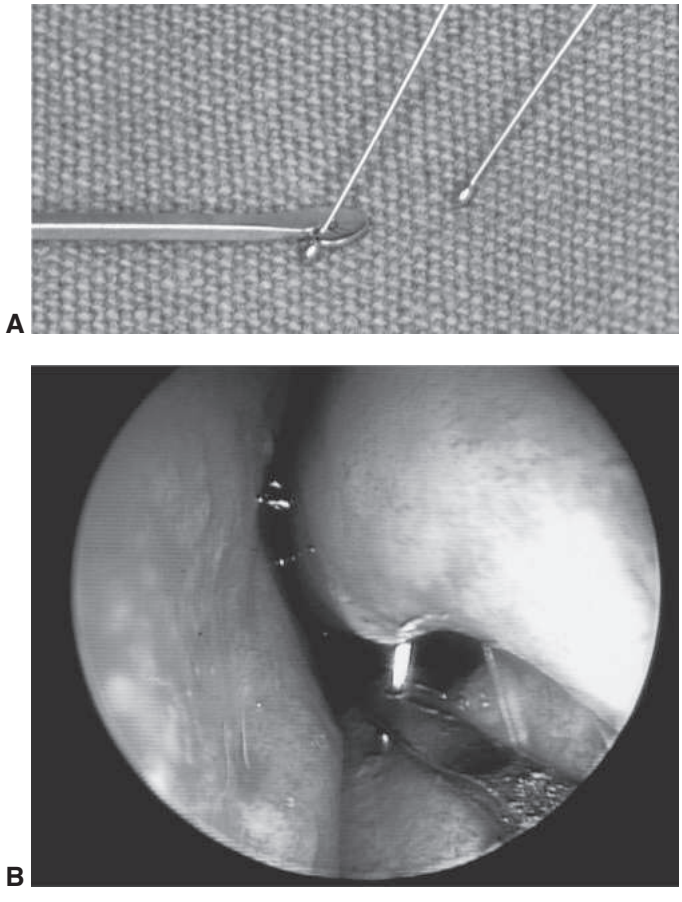

Figure 15-8 Crawford stent and hook. **A,** Hook engaging the "olive tip" of the stent. **B,** Intranasal view of the engaged hook retrieving the stent. *(Reproduced with permission from Nerad JA.* Oculoplastic Surgery: The Requisites in Ophthalmology. *Mosby; 2001:233.)*

remains undefined, in part because the necessary catheter equipment is expensive. Moreover, simple probing has a high success rate, obviating the need for further procedures.

Wladis EJ, Aakalu VK, Yen MT, Bilyk JR, Sobel RK, Mawn LA. Balloon dacryoplasty for congenital nasolacrimal duct obstruction: a report by the American Academy of Ophthalmology. *Ophthalmology.* 2018;125(10)1654–1657.

Turbinate infracture

If the inferior turbinate appears to be lateralized against the NLD at the time of probing and irrigation, medial infracture of the inferior turbinate should be performed. The blunt end of a periosteal elevator is placed within the inferior meatus along the lateral surface of the inferior turbinate. The inferior turbinate is then rotated medially toward the septum. Fracturing the turbinate at its base significantly enlarges the inferior meatus and permits direct visualization of the lacrimal probe tip.

Dacryocystorhinostomy

Dacryocystorhinostomy (DCR) is usually reserved for children who have persistent epiphora following intubation and/or balloon dacryoplasty, children who experience recurrent dacryocystitis, and patients with extensive developmental abnormalities of the nasolacrimal drainage system that prevent probing and intubation. DCR is more fully discussed later in this chapter, in the section Acquired Nasolacrimal Duct Obstruction.

Acquired Lacrimal Drainage Obstruction

Evaluation

History

Patients with acquired tearing can be loosely divided into 2 groups: those with hypersecretion of tears (lacrimation or reflex tearing) and those with impairment of drainage (epiphora). The initial step in evaluating the tearing patient is differentiating between the 2 conditions. The following list aids in the assessment of the patient with acquired tearing:

- constant versus intermittent tearing
- periods of remission versus no remission
- unilateral versus bilateral condition
- subjective ocular surface discomfort
- history of allergies
- use of topical medications such as glaucoma eyedrops
- history of probing during childhood
- prior ocular surface infections such as conjunctivitis or herpes simplex
- prior sinus disease or surgery, midfacial trauma, or nasal fracture
- prior treatment with radioactive iodine for thyroid cancer
- previous episodes of lacrimal sac inflammation
- clear tears versus tears with discharge or blood (hemolacria, Fig 15-10)

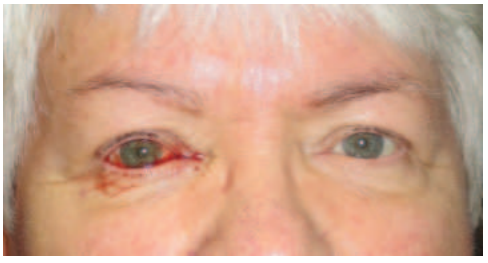

Figure 15-10 Right hemolacria in a patient with lacrimal sac neoplasm. *(Courtesy of Eric A. Steele, MD.)*

Examination

Systematic examination helps pinpoint the cause of acquired tearing. The initial step of the examination is to distinguish patients with obstruction of the lacrimal drainage system from those with secondary hypersecretion.

Pseudoepiphora evaluation *Epiphora* is defined as an overflow of tears. Some patients experience symptoms that they describe as their eyes having "too many tears," but they do not exhibit frank epiphora. These sensations are often caused by other ocular or eyelid abnormalities. For example, patients with dry eyes may perceive foreign-body sensation or increased mucus production as excess tearing. However, they do not exhibit true overflow of tears over the eyelid margin or down the cheek. An assessment for pseudoepiphora includes the following considerations:

- *Tear meniscus.* The size and asymmetry of the lacrimal lake and presence of precipitated proteins and stringy mucus may indicate an abnormal tear film or outflow obstruction.
- *Tear breakup time.* To determine tear breakup time, fluorescein dye is instilled, and the patient is asked to refrain from blinking. The tear film is examined using a broad beam of a slit lamp with a cobalt-blue filter. A tear-film breakup time of less than 10 seconds may indicate poor function of the mucin or meibomian layer despite a sufficient amount of tears.
- *Evaluation of corneal and conjunctival epithelium.* Topical rose-bengal and lissamine-green dyes can aid in the detection of subtle ocular surface abnormalities by staining devitalized conjunctival and corneal epithelium. Fluorescein staining indicates more severe tear film malfunction with epithelial loss.
- *Basal tear secretion.* Basal tear secretion can be measured with Schirmer testing (Fig 15-11). (See also BCSC Section 8, *External Disease and Cornea,* for further discussion of tear film tests and tear film abnormalities.)
- *Corneal irritation.* Irritation of the ocular surface is a common cause of secondary hypersecretion. This can be seen in individuals with misdirected eyelashes (trichiasis, distichiasis) or eyelid malposition (entropion). Other ocular irritants include allergy, chronic infection (eg, chlamydia or molluscum), and giant papillary conjunctivitis from contact lens wear. Careful examination of the palpebral conjunctiva can aid in the identification of such disorders.

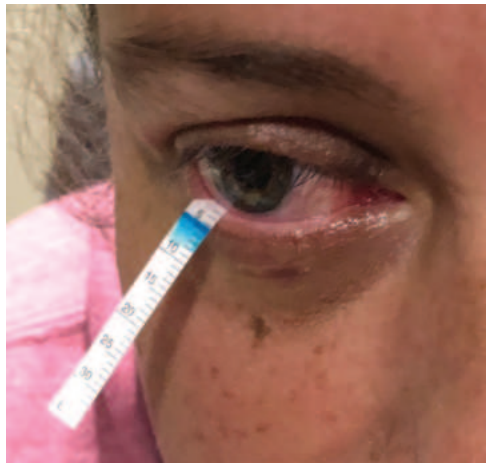

Figure 15-11 The basal secretion test as measured with a Schirmer strip. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Lacrimal outflow examination

Examination of a patient with abnormal lacrimal outflow begins with an observation of the eyelid and puncta positions during the blink cycle. Facial nerve dysfunction can result in a weakened blink and poor lacrimal pump function. An enlarged caruncle or conjunctivochalasis (Fig 15-12) can also mechanically block the aperture of the puncta and lead to tearing. Punctal stenosis, occlusion, or aplasia may be present.

Palpation of the lacrimal sac may cause reflux of mucoid or mucopurulent material through the canalicular system, confirming complete NLDO. Further diagnostic tests are needed if a lacrimal sac tumor is suspected. Nasal examination may uncover an unsuspected cause of the epiphora, such as an intranasal tumor or polyp, turbinate impaction, deviated septum, or chronic allergic rhinitis. These conditions may occlude the nasal end of the NLD.

Diagnostic tests

The clinical evaluation of the lacrimal drainage system historically comprised a *dye disappearance test (DDT)* followed by the Jones I test (swabbing the inferior meatus to see if dye passes through physiologically) and the Jones II test (irrigating with saline and assessing the passage of fluid and presence or absence of dye). Although some clinicians continue to rely on formal Jones testing, most use a simplified approach involving only the DDT and lacrimal irrigation.

The DDT is useful for assessing the presence or absence of adequate lacrimal outflow, especially in unilateral cases. It is more heavily relied upon for children, in whom lacrimal irrigation is difficult without deep sedation. Fluorescein is instilled in both eyes, and the tear film is observed with the cobalt-blue filter. Persistence of significant dye over a 5-minute period implies decreased outflow. Asymmetry in dye clearance during the DDT can be a particularly helpful diagnostic clue (Fig 15-13). If the DDT result is normal, severe lacrimal drainage dysfunction is unlikely. However, intermittent causes of tearing, such as an allergy, dacryolith, or intranasal obstruction, cannot be ruled out.

Lacrimal drainage system irrigation is most frequently performed after the DDT to determine the level of obstruction (Video 15-1). After instillation of topical anesthesia, the

inferior punctum is dilated if needed, and the irrigating cannula is placed in the canalicular system. To prevent canalicular kinking and difficulty in advancing the irrigating cannula, the clinician maintains lateral traction of the lower eyelid (see Fig 15-6). Canalicular stenosis or occlusion should be recorded and confirmed by subsequent diagnostic probing. Once the irrigating cannula has been advanced into the horizontal canaliculus, clear saline is injected, and the pattern of flow is noted. Careful observation and interpretation determine the site of obstruction without additional testing.

VIDEO 15-1 Lacrimal dilation and irrigation. *Courtesy of Eric A. Steele, MD.*

Difficulty advancing the irrigating cannula and an inability to irrigate fluid suggest *total canalicular obstruction.* If saline can be irrigated successfully but it refluxes through the upper canalicular system and no distention of the lacrimal sac is observed on palpation, *complete blockage of the common canaliculus* is probable (Figs 15-14, 15-15). Subsequent probing determines whether the common canalicular stenosis is total or whether it can be dilated. If mucoid material or saline refluxes through the opposite punctum and lacrimal sac distention is palpable, the diagnosis is *complete NLDO* (Video 15-2). If saline irrigation is not associated with canalicular reflux or fluid passing down the NLD, the lacrimal sac will become distended, causing the patient discomfort. This result confirms a complete NLDO with a functional valve of Rosenmüller; this combination prevents reflux through the canalicular system. A combination of simultaneous saline reflux through the opposite canaliculus and saline irrigation through the NLD into the nose may indicate a *partial NLD stenosis.*

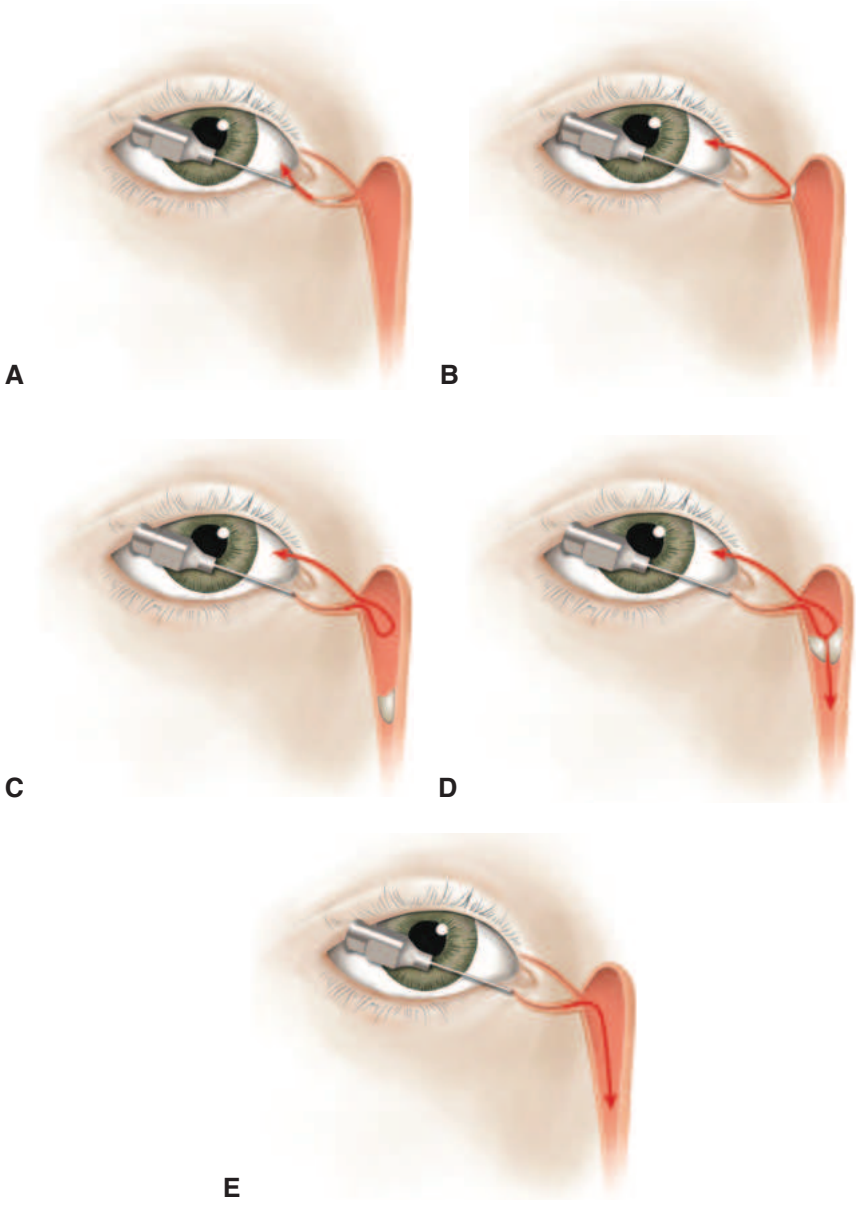

Figure 15-14 Lacrimal drainage system irrigation. **A,** Complete canalicular obstruction. The cannula is advanced with difficulty, and irrigation fluid refluxes from the same canaliculus. **B,** Complete common canalicular obstruction. A "soft stop" is encountered at the level of the common canaliculus, and irrigated fluid refluxes through the opposite punctum and sometimes partially from the same canaliculus as well. **C,** Complete nasolacrimal duct obstruction (NLDO). The cannula is easily advanced to the medial wall of the lacrimal sac; then a "hard stop" is felt, and irrigation fluid refluxes through the opposite punctum. Often, the refluxed fluid contains mucus and/or pus. With a tight valve of Rosenmüller, lacrimal sac distention without reflux of irrigation fluid may occur. **D,** Partial NLDO. The cannula is easily placed, and irrigation fluid passes into the nose as well as refluxing through the opposite punctum. **E,** Patent lacrimal drainage system. The cannula is placed with ease, and most of the irrigation fluid passes into the nose. *(Illustration by Cyndie C. H. Wooley.)*

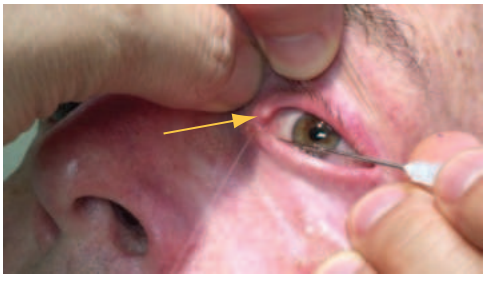

Figure 15-15 Lacrimal irrigation through the inferior canaliculus shows complete reflux through the superior canaliculus *(arrow)*, indicative of a complete NLDO (hard stop is noted along the medial wall of the lacrimal fossa). *(Courtesy of Bobby S. Korn, MD, PhD.)*

VIDEO 15-2 Lacrimal irrigation showing a complete nasolacrimal duct obstruction.
Courtesy of Bobby S. Korn, MD, PhD.

If saline irrigation passes freely into the nose with no reflux through the canalicular system, an anatomically *patent nasolacrimal drainage system* is present. However, it is important to note that even though this irrigation is successful under increased hydrostatic pressure from the irrigating syringe, a *functional obstruction* may still be present. A dacryolith may also impair tear flow without blocking irrigation.

Diagnostic probing of the upper system (puncta, canaliculi, and lacrimal sac) is useful in confirming the level of obstruction. In adults, this procedure can be performed easily with topical anesthesia. A small probe is used initially to detect any canalicular obstruction. If an obstruction is encountered, the probe is clamped at the punctum before withdrawal, thereby measuring the distance to the obstruction. A larger probe may be useful to determine the extent of a partial obstruction, but the probe should not be forced through any area of resistance.

Diagnostic probing of the NLD is not used in adults because there are other means of diagnosing NLDO. In addition, probing in adults has limited therapeutic value because it rarely produces lasting patency. In contrast, probing in infants is a useful and largely successful procedure. This reflects the differing pathophysiologies of congenital NLDO and acquired NLDO: the former often results from occlusion of the distal end of the NLD by a thin membrane, while the latter is caused by extensive fibrosis of the duct itself.

Intranasal examination is performed with a nasal speculum and light source. Diagnostic nasal endoscopy can be helpful in the evaluation of the nasal anatomy and in the identification of disease processes.

Contrast dacryocystography and *dacryoscintigraphy* are alternative methods of evaluation. Contrast dacryocystography, which involves injection of dye into the lacrimal system followed by computerized digital subtraction imaging, provides anatomical information of any obstructed sites. In dacryoscintigraphy, a physiologic picture of lacrimal outflow is obtained by using radionucleotide eyedrops to follow tear flow on a scintigram.

Computed tomography (CT) and *MRI* are useful in the evaluation of craniofacial injury, congenital craniofacial deformities, and suspected neoplasia. CT is superior for the evaluation of suspected bony abnormalities, such as fractures. MRI is superior for the evaluation

of suspected soft-tissue disease, such as malignancy. Either CT or MRI may be helpful in evaluating concomitant sinus or nasal disease that may contribute to excess tearing.

Punctal Disorders

Several punctal abnormalities can result in epiphora. Puncta may be stenotic, enlarged (usually iatrogenic), malpositioned, or occluded by adjacent structures.

Punctal stenosis and occlusion can be due to numerous causes, including

- congenital conditions
- inflammatory diseases
  - posterior blepharitis
  - Stevens-Johnson syndrome
  - mucous membrane pemphigoid (ocular cicatricial pemphigoid)
- infectious diseases (eg, herpes)
- iatrogenic causes
  - glaucoma medications
  - deliberate occlusion in the treatment of dry eye disease (plugs, cautery)

Punctal stenosis may be associated with punctal ectropion or atrophy in the absence of tear flow. It may be treated with dilation, punctoplasty, or stenting. Most often, the benefits of dilation are short-lived, and punctoplasty is required. This is usually accomplished with a snip procedure, in which a small portion of the ampulla is excised. If stenosis recurs, stenting may be required during healing to prevent contraction. Treatment of complete occlusion consists of surgical canalization and, in most cases, stenting.

Abnormally large puncta can also cause epiphora due to disruption of the lacrimal pump. The expanded opening prevents formation of an adequate seal when the eyes are closed, interfering with the usual development of negative pressure needed to drain the tears. Punctal enlargement is typically iatrogenic in nature and can occur from "cheese-wiring" of a stent secured too tight intranasally (Fig 15-16), punctoplasty, excision of adjacent lesions, or even from rough dilation and probing that cause damage to the normal fibrous ring around the punctum. Damage to the puncta may be difficult to correct.

If the punctum is not in the tear lake, the anatomical abnormality (most commonly ectropion) must be addressed by a medial spindle conjunctivoplasty or horizontal eyelid tightening (see Chapter 12 in this volume for more on both topics). Punctal stenosis may require punctoplasty. Puncta may also become obstructed by adjacent structures, such as

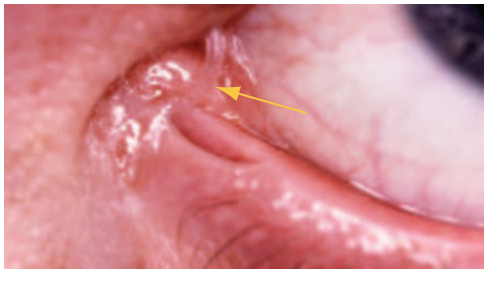

Figure 15-16 Inferior punctal elongation caused by tight intranasal fixation of a bicanalicular lacrimal stent *(arrow)*. *(Courtesy of Don O. Kikkawa, MD.)*

a hypertrophied caruncle or conjunctivochalasis (see Fig 15-12), which can be corrected by reducing excess tissue.

Canalicular Obstruction

Evaluation

Obstruction can occur within the upper, lower, or common canaliculus. The location of the obstruction is detected by a tactile soft stop during diagnostic probing (typically, the probe would reach a hard stop in the fossa of the lacrimal sac on contact with the lacrimal bone). *Total common canalicular obstruction* is characterized by high-velocity reflux from the opposite canaliculus (see Figs 15-14, 15-15, and Video 15-2), with no flow into the lacrimal sac during lacrimal system irrigation. *Partial obstruction* may be discovered during lacrimal system irrigation when there is partial fluid flow into the nose and partial reflux around the cannula or through the opposite punctum. In some instances, a partial obstruction may represent a *total functional occlusion* due to weakness of the lacrimal pump or inability of tears to pass through the partial obstruction under normal physiologic conditions (as opposed to the high hydrostatic pressure from irrigation).

Etiology

Lacrimal plugs Punctal and canalicular plugs used in the treatment of dry eye disease come in various shapes and sizes. Punctal plugs that are too small may migrate within the canaliculus and result in obstruction, with associated inflammation or infection. The permanent intracanalicular plug can lead to infection. Even temporary or absorbable plugs have been known to cause a local inflammatory response and canalicular constriction. Canalicular probing is used to identify the location of the problematic plug, which is then surgically excised. Often, excision of a short segment of scarred canaliculus is required, which is then repaired with a technique similar to reconstruction following trauma or after injury of the canaliculus during excision of a neoplasm.

Medication Systemic medications can also cause canalicular obstruction. Chemotherapeutic agents, including 5-fluorouracil and docetaxel, are secreted in the tear film, leading to inflammation and scarring of the canaliculi. Use of topical steroid eyedrops and artificial tears during chemotherapy may prevent scarring. If this condition is identified early—before the obstruction is complete—stents can be placed to prevent progression while the patient completes the course of chemotherapy. A special canalicular-only stent is available for these cases. Less commonly, canalicular obstruction has been reported after the use of topical medication (eg, phospholine iodide, eserine, idoxuridine).

Infection Numerous infections can cause canalicular obstruction. Most frequently, obstruction occurs concurrently with diffuse conjunctival infection (eg, vaccinia virus, herpes simplex virus). Isolated canalicular infection (canaliculitis; discussed later in this chapter) can also result in obstruction.

Inflammatory disease Inflammatory conditions such as mucous membrane pemphigoid (ocular cicatricial pemphigoid), Stevens-Johnson syndrome, and graft-vs-host disease

often cause loss of the puncta and/or canaliculi. However, because of concurrent loss of tear secretion, patients often do not experience epiphora.

Trauma Traumatic injury to the canaliculi can result in permanent damage if the injury is not managed in a timely, appropriate manner.

Neoplasm When a neoplasm is present in the medial canthal area, complete resection may include removal of the puncta and canaliculi. When the distal lacrimal drainage system remains intact, the remaining portion of the canaliculi may be marsupialized to the conjunctival surface with or without lacrimal intubation.

Management

Canalicular stenting *Intubation* or *stenting* of the lacrimal drainage system should be considered as a first-line therapy whenever possible. Intubation of the nasolacrimal drainage system can usually be performed successfully when the patient has symptomatic canalicular constriction but not complete occlusion. For canalicular scarring, the use of a balloon catheter alone is usually not sufficient to correct the condition.

Reconstruction Reconstruction of an obstructed canaliculus is often successful when only a few millimeters are involved. If a limited area of total occlusion is discovered near the punctum, the occluded canaliculus can be resected and the cut ends of the canaliculus anastomosed over a stent. For distal obstructions, including the common canaliculus, trephination with lacrimal stenting can be useful. This is most successful for distal monocanalicular obstructions, followed by distal bicanalicular, common, and proximal obstructions.

Canaliculodacryocystorhinostomy If the common canaliculus is totally obstructed or the lacrimal sac is sclerotic, a canaliculodacryocystorhinostomy or canaliculorhinostomy may be performed. In these procedures, the area of total common canalicular obstruction is removed, and the remaining patent canalicular system is directly anastomosed to the lacrimal sac mucosa or the lateral nasal wall mucosa with placement of a lacrimal stent.

Conjunctivodacryocystorhinostomy When 1 or both canaliculi are severely obstructed, a CDCR may be required. This procedure creates a complete bypass of the lacrimal drainage system. The beginning of this surgical technique is similar to a DCR (described later in this chapter) and is followed by placement of a glass tube through a tract created from the caruncle into the middle nasal meatus. The surgeon should have tubes of different lengths available at the time of surgery to ensure implantation of a tube that emerges clearly in the nose without abutting the nasal septum (Video 15-3, Fig 15-17).

VIDEO 15-3 Conjunctivodacryocystorhinostomy with Jones tube.
Courtesy of Don O. Kikkawa, MD

A diligent discussion of eyelid hygiene and tube maintenance is imperative prior to surgery because postoperative care can be troublesome and frustrating for the patient. A daily routine consisting of nasal lavage with saline solution and "snuffing" of artificial

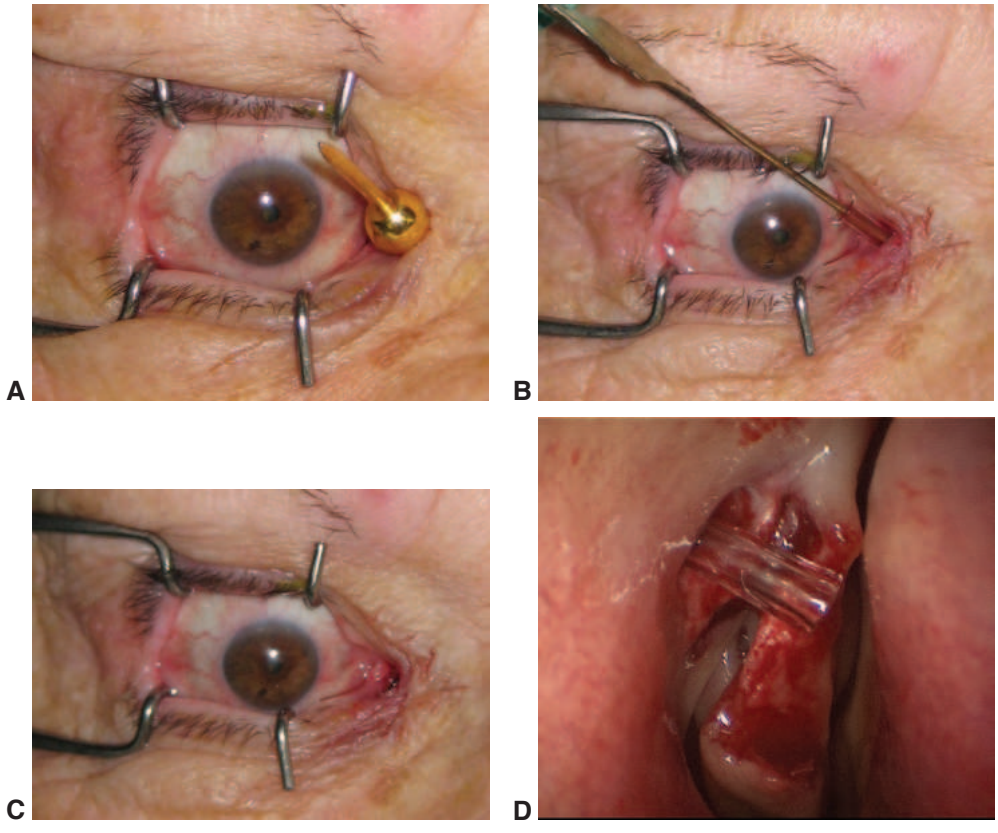

Figure 15-17 Conjunctivodacryocystorhinostomy. **A,** The surgical tract is enlarged with a gold dilator. **B,** The glass (Jones) tube is introduced into the tract using a Bowman probe as a guide. **C,** External view of the well-positioned tube. **D,** Endoscopic view of the well-positioned tube. *(Parts A–C courtesy of Morris E. Hartstein; part D courtesy of Eric A. Steele, MD.)*

tears through the tube can clear mucus debris and prevent obstruction. During office examination, irrigation of saline through the tube may clear any clogging from proteinaceous debris. In general, a tube that is well tolerated and functional does not require removal. Periodically, it may require replacement; if this is necessary, the appropriate size should be available for immediate replacement to avoid contracture of the CDCR tract. Patients with obstructive sleep apnea may be bothered by air reflux onto the ocular surface from the continuous positive airway pressure machine. This can sometimes be alleviated by switching to a full-face mask, but may be so bothersome that tube removal is necessary. Despite these drawbacks, CDCR helps many patients with otherwise intractable epiphora.

Acquired Nasolacrimal Duct Obstruction

An NLDO usually can be diagnosed with irrigation. By and large, NLDO is a relatively benign condition, and clinicians tend to proceed directly to a discussion of surgery. Although most cases are routine, alternative causes of NLDO merit consideration.

Etiology

Involutional stenosis Involutional stenosis is probably the most common cause of NLDO. It affects women twice as frequently as men. Although the inciting event in this process is unknown, clinicopathologic study suggests that inflammatory infiltrates and edema cause compression of the lumen of the NLD. This may be the result of anatomical predisposition, unidentified infection, or possibly autoimmune disease. Management almost always consists of DCR.

Dacryolith Dacryoliths, or concretions formed within the lacrimal sac (Fig 15-18), can also obstruct the NLD. Dacryoliths consist of shed epithelial cells, lipids, and amorphous debris with or without calcium. In most cases, no inciting event or abnormality is identified. Occasionally, infection with *Actinomyces israelii* or *Candida* species or long-term administration of topical medications such as epinephrine can lead to the formation of concretions. Depending on their position, they can sometimes result in intermittent NLDO symptoms, and acute impaction of a dacryolith in the NLD can produce lacrimal sac distention and pain. Dacryoliths are easily removed during DCR.

Sinus and nasal disease Sinus disease often occurs in conjunction with, and may contribute to, the development of NLDO. Clinicians should inquire about previous sinus surgery because the NLD is sometimes inadvertently damaged during sinus procedures. Similarly, nasal conditions such as polyps, chronic congestion, a deviated septum, and prior nasal surgery can also contribute to NLDO.

Trauma Naso-orbital fractures may involve the NLD. Early treatment with fracture reduction and stenting of the entire lacrimal drainage system should be considered. However, such injuries are often not recognized or are initially neglected while more serious injuries are managed. Injuries may also occur during rhinoplasty or endoscopic sinus surgery. In these cases, late treatment of persistent epiphora usually requires DCR.

Inflammatory disease Granulomatous disease, including sarcoidosis, granulomatosis with polyangiitis (Fig 15-19), and extranodal NK/T-cell lymphoma, may also lead to NLDO. When systemic disease is suspected, a biopsy of the lacrimal sac or the NLD performed at the time of DCR may provide additional diagnostic input.

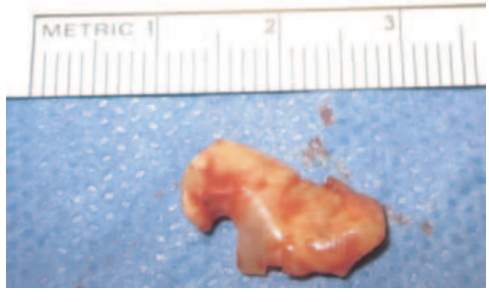

Figure 15-18 Lacrimal sac dacryolith associated with NLDO. *(Courtesy of Eric A. Steele, MD.)*

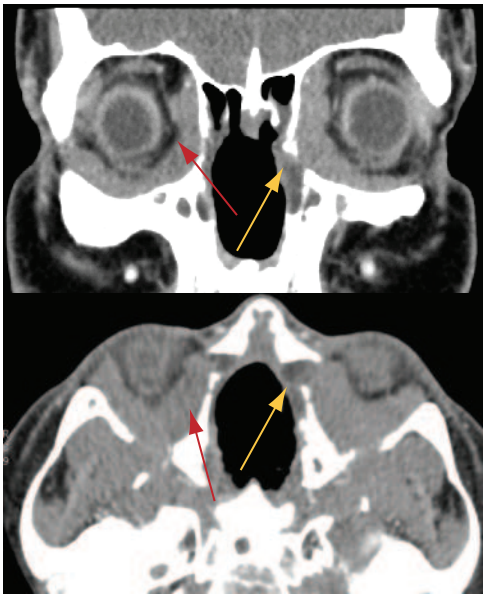

Figure 15-19 CT scans of a patient demonstrating bilateral orbital granulomatosis with polyangiitis *(red arrows)* and secondary nasolacrimal duct obstruction *(yellow arrows).* *(Courtesy of Bobby S. Korn, MD, PhD.)*

Lacrimal plugs Dislodged punctal and canalicular plugs can migrate and occlude the NLD. As with most forms of NLDO, treatment consists of DCR. Retained segments of an incompletely removed lacrimal stent may also cause NLDO.

Radioactive iodine Therapeutic radioactive iodine for the treatment of thyroid cancer may also lead to closure of the lacrimal apparatus because of local uptake by the Na^+/I (sodium/iodide) symporter (NIS) found in the mucosa of the sac and duct. This is not seen with the lower dosages used to treat the thyroid gland in patients with autoimmune hyperthyroidism (Graves disease).

Neoplasm Neoplasm should be considered as a possible etiology in any patient presenting with NLDO. In patients with an atypical presentation, including younger age and male sex, further workup should be considered. Hemolacria (see Fig 15-10) as well as lacrimal sac distention above the medial canthal tendon are suggestive of neoplasm. A history of malignancy, especially of sinus or nasopharyngeal origin, warrants further investigation. When malignancy is suspected, appropriate imaging studies (CT and/or MRI) should be obtained. Preoperative endoscopy can be performed to evaluate for intranasal neoplasm. In addition, if an unexpected mass or other abnormality suggestive of neoplasm is encountered during surgery, a biopsy specimen should be obtained.

When a neoplasm is found to contribute to NLDO, initial treatment focuses on the tumor. In patients with a benign tumor, a DCR or CDCR can be performed. In patients with a malignant tumor, the surgical correction of the nasolacrimal drainage system should be postponed until there is certainty of clear margins or there is a disease-free interval, after which a DCR or CDCR may be undertaken. Tumors of the lacrimal sac and NLD are discussed in further detail later in this chapter, in the section titled Neoplasm.

Management

Intubation and stenting Partial stenosis of the NLD with symptomatic epiphora may respond to surgical intubation of the entire lacrimal drainage system. This procedure should be performed only if the tubes can be passed easily. In cases of complete NLDO, intubation alone is not effective, and a DCR should be considered.

Dacryocystorhinostomy A DCR is the treatment of choice for most patients with acquired NLDO. Surgical indications include recurrent dacryocystitis, chronic mucoid reflux, painful distention of the lacrimal sac, and bothersome epiphora. For patients with dacryocystitis, active infection should be treated, if possible, before a DCR is performed.

Although there are many variations in surgical techniques, all of them create an anastomosis between the lacrimal sac and the nasal cavity through a bony ostium. One significant distinction among techniques is whether the surgeon uses an internal (intranasal) approach or the more traditional external (transcutaneous) approach. In both approaches, bicanalicular lacrimal stenting is usually performed at the end of the procedure.

Recent data indicate similar success rates for the 2 approaches. The advantages of an *internal (endonasal) DCR* include lack of a visible scar, a shorter recovery period, and less discomfort. An *external DCR* may allow better exposure for management of canalicular stenosis, unexpected neoplasm, or dacryoliths.

DCR can be performed under general anesthesia or local anesthesia with intravenous sedation. Intraoperative hemostasis can be enhanced by preoperative injection of lidocaine with epinephrine into the medial canthal soft tissues and by the use of intranasally injected anesthetic and nasal packing with vasoconstrictive agents (eg, oxymetazoline hydrochloride, phenylephrine, epinephrine, or cocaine hydrochloride). In external DCR (Figs 15-20, 15-21), the skin incision should be made to avoid the angular blood vessels and prevent wound contractures leading to epicanthal folds. The osteotomy adjacent to the medial wall of the lacrimal sac can be created with a hemostat, rongeur, trephine, or drill. An anteriorly positioned ethmoidal air cell may require removal to properly drain into the nasal cavity. A large osteotomy site facilitates the formation of posterior and anterior mucosal flaps from both the lacrimal sac and the nasal mucosa. To avoid scarring and subsequent failure of the procedure, it is important for the surgeon to minimize trauma to the common internal ostium of the canaliculi when the lacrimal sac flaps are created. Suturing of the corresponding posterior flaps and anterior flaps is common, but sometimes only anterior flaps are anastomosed.

Endonasal DCR consists of removal of the nasal mucosa over the area corresponding to the nasolacrimal sac and duct (Fig 15-22), followed by an osteotomy to remove the frontal process of the maxillary bone and the lacrimal bone that cover the lacrimal sac (Video 15-4). To allow proper exposure of the lacrimal sac, the surgeon may also need to remove the uncinate process or an anteriorly located ethmoidal air cell. The lacrimal sac is then opened, and the medial wall of the sac is removed; this marsupializes the sac into the nose. Careful selection of patients with adequate nasal cavities is crucial for success, and the surgeon should be prepared to modify the nasal anatomy for better exposure and access (eg, by performing nasal septoplasty). Several variations of endonasal DCR exist,

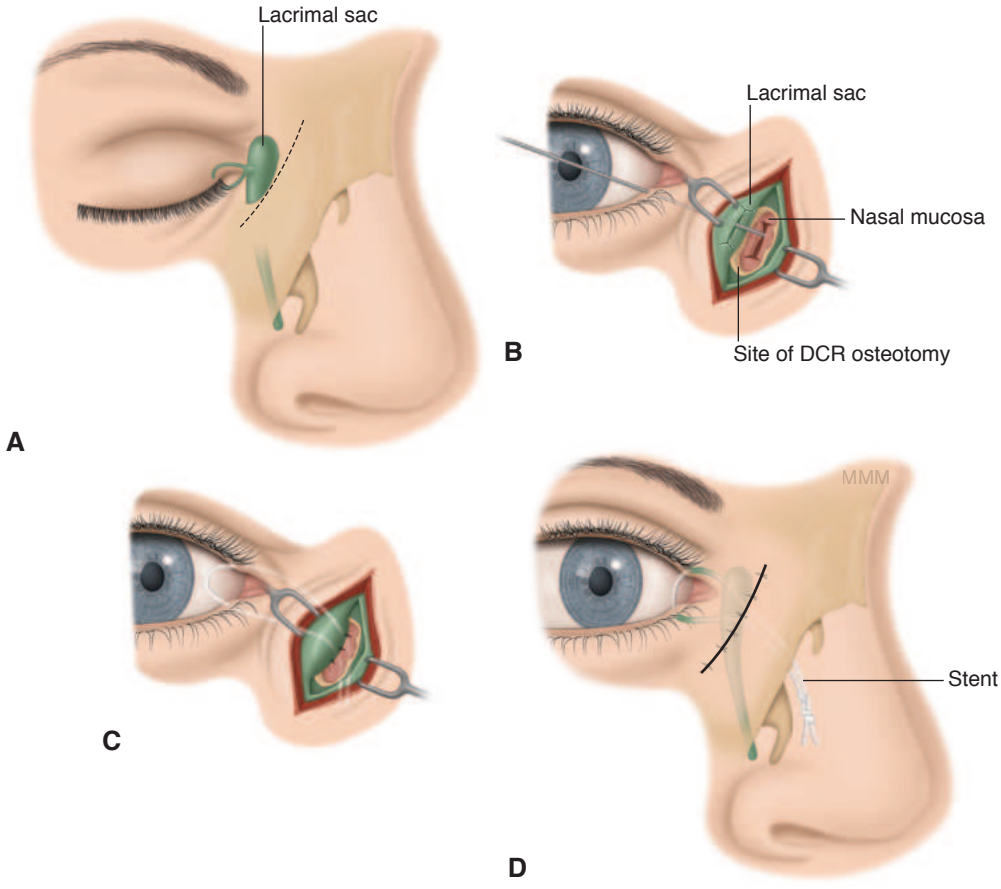

Figure 15-20 External dacryocystorhinostomy (DCR). **A,** The incision is marked 10 mm from the medial canthus, starting just above the medial canthal tendon and extending inferiorly. **B,** Bone from the lacrimal fossa and anterior lacrimal crest has been resected. Flaps have been fashioned in the nasal mucosa. including direct visualization or visualization with the use of an endoscope *(endoscopic DCR)*. Some surgeons use a fiber-optic probe passed through a canaliculus to transilluminate the lacrimal sac.

VIDEO 15-4 Endonasal dacryocystorhinostomy.
Courtesy of Bobby S. Korn, MD, PhD.

Although DCRs are successful in most patients, failures do occur. DCR failures may be caused by fibrosis and occlusion of the osteotomy; common canalicular obstruction; incomplete opening of the inferior lacrimal sac, which causes a sump syndrome (Fig 15-23A); inappropriate placement or size of the bony ostium; or scarring between the soft tissue

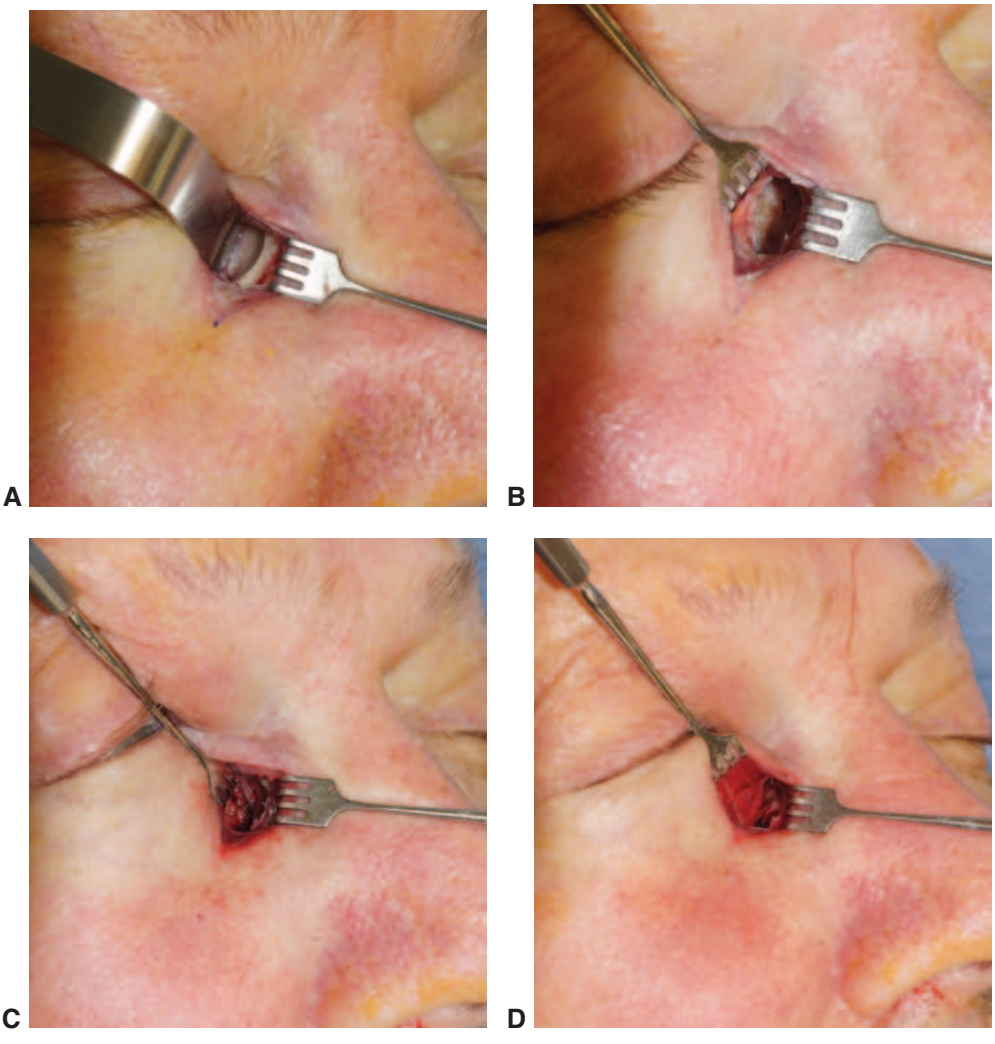

Figure 15-21 External DCR surgical series. **A,** Exposure of the anterior lacrimal crest. **B,** After osteotomy to expose the lacrimal sac. **C,** After fenestration of the lacrimal sac and stent placement. **D,** After suture fixation of the lacrimal and nasal mucosal flaps. *(Courtesy of Steven M. Couch, MD.)*

ostium and the nasal septum. Treatment of a sump syndrome is aimed toward removal of this residual inferior bone through an external or endonasal approach (Fig 15-23B). The outcome of the DCR is also influenced by other factors, including the patient's history of trauma, coexisting autoimmune inflammatory disease, the presence of active dacryocystitis, the development of postoperative infection, and hypersensitivity or foreign-body reactions to the stent. When an initial DCR fails, some surgeons apply topical mitomycin to the surgical site during reoperation. This potent antiproliferative alkylating agent helps prevent fibrosis at the osteotomy site.

Microendoscopy with lacrimal duct recanalization The use of a microendoscope allows for exploration and direct visualization of NLDOs as well as minimally invasive

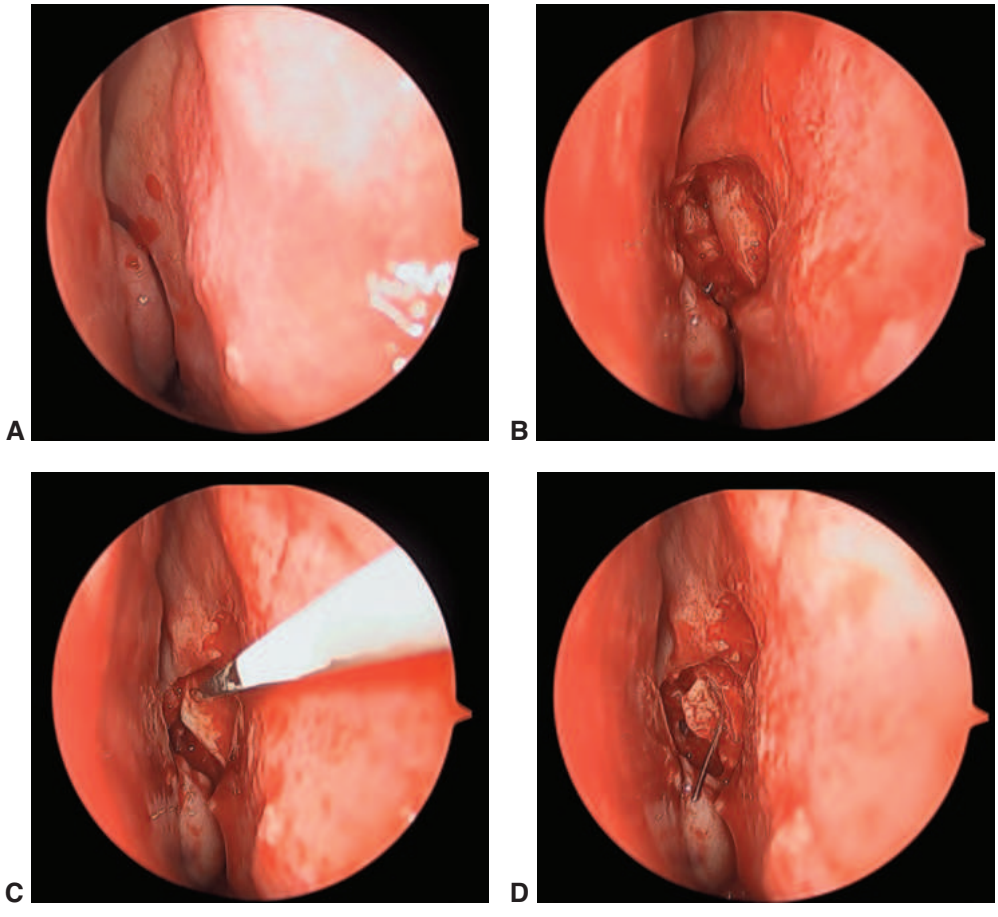

Figure 15-22 Endonasal DCR surgical series. **A,** Endonasal view. **B,** View after osteotomy of the frontal process of the maxilla. **C,** Marsupialization of the lacrimal sac**. D,** Placement of the Bowman probe prior to stent placement. *(Courtesy of Lilangi Ediriwickrema, MD.)*

therapeutic techniques such as laser dacryoplasty and microdrill dacryoplasty to reopen the NLD. These interventions attempt to maintain the anatomy of lacrimal drainage system with a focal surgical intervention for recanalization. Some studies have reported success rates nearing those for DCR. The use of this technology is not widespread because regulatory approval has not yet been given.

Mihailovic N, Blumberg AF, Rosenberger F, et al. Long-term outcome of transcanalicular microdrill dacryoplasty: a minimally invasive alternative for dacryocystorhinostomy. *Br J Ophthalmol.* 2021;105(11):1480–1484.

Therapeutic Closure of the Lacrimal Drainage System

In cases of severe dry eye disease, occlusion of the lacrimal puncta may be helpful. Dissolvable collagen plugs may be used on a trial basis, or permanent silicone plugs may be used. Permanent intracanalicular plugs are not recommended. Although punctal plugs are usually well tolerated, complications are occasionally encountered. Minor problems include ocular surface irritation and a foreign-body reaction. Pyogenic granulomas may develop, requiring removal of the plugs. More serious complications usually relate to plug displacement.

Plug extrusion or *migration* is not uncommon. The ophthalmologist can best avoid these complications by using a plugs that are the appropriate size. When appropriately fitted, punctal plugs usually stay in place. However, if a plug migrates within the lacrimal drainage system, obstruction of either the canaliculus or the NLD can result. *Canaliculitis* may result from canalicular plugs or from punctal plugs that have migrated into the canaliculus.

When occlusion with plugs is not successful, the clinician may consider surgical occlusion. Surgery is typically reserved for severe cases and must be performed with caution. Once the decision has been made to proceed with surgical occlusion, the puncta are closed in a stepwise fashion, one punctum at a time.

There are numerous surgical techniques for occluding the lacrimal drainage system. *Thermal obliteration* of the puncta and adjacent canaliculi can be performed with a handheld cautery unit or a needle-tip unipolar cautery unit. *Ampullectomy* can be performed with either direct closure or placement of an overlying conjunctival graft. Often, despite aggressive attempts, the puncta persist or reform. In these recalcitrant cases, the punctal and adjacent canalicular epithelia can be completely excised, or the canaliculus can be transected and reconstructed with the severed ends offset from one another.

Trauma

Canaliculus

Traumatic injuries to the canaliculi occur either by direct laceration or by avulsion, when sudden lateral displacement of the eyelid tears the medial canthal tendon and associated canaliculus. Because it lacks tarsal support, the canaliculus lies within the weakest part of the eyelid and is often the first structure to yield. Therefore, when such an injury is suspected in cases of trauma, careful inspection of this area is mandatory, including diagnostic canalicular

probing and irrigation. Because the success rate of primary repair is much higher than that of secondary reconstruction, most surgeons recommend repair of all canalicular lacerations.

The first step of the repair is locating the severed ends of the canalicular system. General anesthesia and magnification with optimal illumination facilitate the search. A thorough understanding of the medial canthal anatomy guides the surgeon to the appropriate area to begin exploration for the medial end of the severed canaliculus. Laterally, the canaliculus is located near the eyelid margin, but for lacerations close to the lacrimal sac, the canaliculus is deep to the anterior limb of the medial canthal tendon (see Chapter 11, Fig 11-4). Irrigation using air, fluorescein, or yellow viscoelastic material through an intact adjacent canaliculus may be helpful. The use of methylene blue dye should be avoided, as it tends to stain the entire operative field. In difficult cases, the careful use of a smooth-tipped pigtail probe may help identify the medial cut end. The probe is introduced through the opposite, uninvolved punctum; passed through the common canaliculus; and finally passed through the medial cut end.

Stenting of the injured canaliculus is essential to help prevent postoperative canalicular strictures. By placing the stent on traction after it has been passed through the NLD, the surgeon draws together the severed canalicular ends and other soft-tissue structures, situating them back in their normal anatomical positions. Direct anastomosis of the canaliculus over the lacrimal stent can be accomplished with closure of the pericanalicular tissues, and the medial canthal tendon and eyelid margin can be reconstructed as necessary.

Traditionally, bicanalicular stents have been used, but monocanalicular stents are also available. One type of monocanalicular stent is attached distally to a metal guiding probe that is retrieved intranasally. Another type is inserted into the punctum and threaded directly into the lacerated canaliculus to bridge the laceration but does not extend into the nose. This allows the procedure to be performed under local anesthesia in the office or the emergency department.

Stents are typically left in place for 3 months or longer. However, cheese-wiring, ocular irritation, infection, local inflammation, or pyogenic granuloma formation may necessitate early removal. Bicanalicular stents are usually cut at the medial canthus and retrieved from the nose. Monocanalicular stents are simply retrieved from the punctum.

Lacrimal Sac and Nasolacrimal Duct

The lacrimal sac and NLD may be injured by direct laceration or by fracture of the surrounding bones. Injuries of the lacrimal sac or NLD may also occur during rhinoplasty or endoscopic sinus surgery when the physiologic maxillary sinus ostium is being enlarged anteriorly. Alternatively, placement of maxillofacial hardware during midface reconstruction or fracture repair may result in violation of the nasolacrimal anatomy with resultant obstruction. Early treatment of the lacrimal sac and NLD is appropriate and consists of fracture reduction, soft-tissue repair, and lacrimal intubation of the entire drainage system. Late treatment of persistent epiphora may require DCR.

Kang JM, Kalin-Hajdu E, Idowu OO, Vagefi MR, Kersten RC. Nasolacrimal Obstruction Following the Placement of Maxillofacial Hardware. *Craniomaxillofac Trauma Reconstr.* 2020;13(1):32–37.

Infection

Dacryoadenitis

Acute inflammation of the lacrimal gland *(dacryoadenitis)* is most often seen in association with inflammatory disease and occasionally is the consequence of malignancy, such as lymphoproliferative disease. Noninfectious disease of the lacrimal gland is covered in Chapter 4. Infectious dacryoadenitis is unusual, and gross purulence and abscess formation are uncommon. However, with the emergence of community-acquired methicillin-resistant *Staphylococcus aureus (MRSA),* this condition is seen more frequently. Most cases are the result of bacterial infection, which may develop secondary to an adjacent infection, after trauma, or hematogenously. Alternatively, MRSA infection may appear without preexisting risk factors. Given the rare occurrence of these infections, large case series are lacking. Presumably, most infections are due to gram-positive bacteria, but cases resulting from gram-negative bacteria have been documented as have rare reports of tuberculosis dacryoadenitis. Epstein-Barr virus is the most frequently reported viral pathogen. Many nonsuppurative cases are treated empirically, without isolation of the alleged pathogen; coverage for MRSA infection in such cases should be considered.

Canaliculitis

Canaliculitis presents with persistent weeping and discharge, sometimes accompanied by a follicular conjunctivitis centered in the medial canthus. The punctum is often erythematous and dilated, or "pouting." A cotton-tipped applicator can be used to apply pressure to the canaliculus ("milking"). The expression of purulent discharge confirms the diagnosis (Fig 15-24). A variety of bacteria, viruses, and mycotic organisms can cause infection within the canaliculus, most commonly *Actinomyces israelii.*

Canaliculitis can be difficult to eradicate. Conservative management consists of warm compresses, digital compression, and topical and sometimes oral antibiotic therapy. Culture of the discharge may be useful in identifying the cause of the infection. Many patients require more aggressive treatment, particularly those with dacryoliths or a retained intracanalicular plug, which can prevent eradication of the organism. Curettage through the punctum is sometimes successful at removing multiple stones, but often a canaliculotomy is required to completely remove all particulate matter. Drainage can be facilitated by an incision through the puncta or through the canaliculus (Video 15-5). The incision is left open to heal by second intention and does not usually require stenting. Some surgeons irrigate or paint the canaliculus with povidone-iodine or irrigate with specially formulated penicillin-fortified eyedrops perioperatively.

Korn, MD, PhD; part D courtesy of Eric A. Steele, MD.)*

Dacryocystitis

Inflammation of the lacrimal sac *(acute dacryocystitis)* is usually due to complete NLDO, which prevents normal drainage from the lacrimal sac into the nose. Chronic tear retention and stasis lead to secondary infection. Clinical findings include edema and erythema with distention of the lacrimal sac (Fig 15-25). The degree of discomfort ranges from none to severe pain. Complications include dacryocystocele formation, chronic conjunctivitis, and spread to adjacent structures (orbital or facial cellulitis).

The following treatments may be used to address acute dacryocystitis:

- *Oral antibiotics.* Oral antibiotics are effective for most infections. Gram-positive bacteria are the most common cause of acute dacryocystitis. However, the clinician should suspect gram-negative organisms in patients who have diabetes mellitus or are immunocompromised and in those who have been exposed to atypical pathogens (eg, individuals residing in nursing homes).

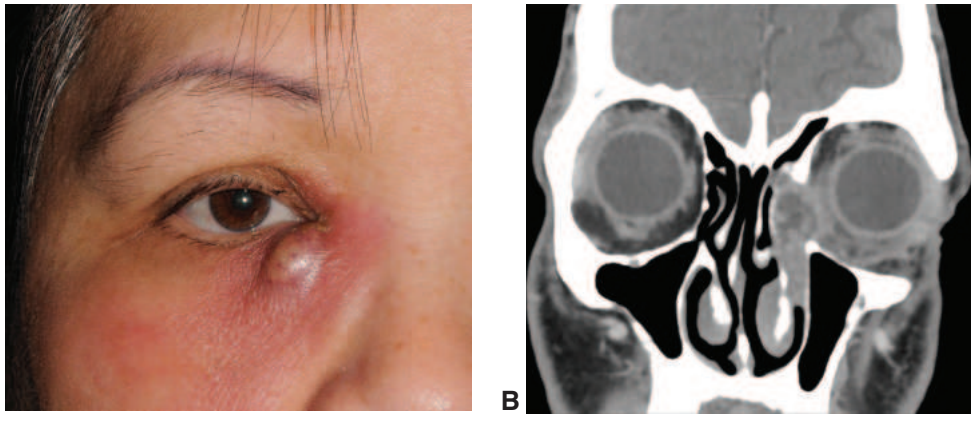

Figure 15-25 Acute dacryocystitis. **A,** Acute dacryocystitis of the right side associated with NLDO. **B,** Coronal CT scan showing acute dacryocystitis of the left side. *(Part A courtesy of Bobby S. Korn, MD, PhD; part B courtesy of Steven M. Couch, MD.)*

- *Parenteral antibiotics.* Parenteral antibiotics may be necessary for the treatment of severe cases, especially if cellulitis or orbital extension is present.
- *Incision and drainage.* A localized abscess involving the lacrimal sac and adjacent soft tissues may require incision and drainage but should be reserved for cases that do not respond to more conservative measures or for patients in severe discomfort.
- *Aspiration of the lacrimal sac.* This procedure may be performed if a pyocele or mucocele is localized and approaching the skin. Smears and cultures of the aspirate may inform the selection of systemic antibiotic therapy.
- *Irrigation or probing.* Irrigation or probing of the canalicular system should be avoided until the infection subsides. In most cases, irrigation is not needed to establish the diagnosis, and it is extremely painful for patients with active infection. Probing of the NLD is not indicated in adults with acute dacryocystitis.
- *Application of topical antibiotics.* Topical antibiotics are of limited value. They do not reach the site of the infection because of stasis within the lacrimal drainage system. They also do not penetrate sufficiently within the adjacent soft tissue.

Dacryocystitis indicating total NLDO requires a DCR in most cases because of inevitable persistent epiphora and recurrent infection. In general, external surgery is deferred until the acute inflammation is resolved. However, endonasal DCR can safely be performed for acute infection. Some patients, however, continue to have a subacute infection until definitive drainage surgery is performed.

Chronic dacryocystitis, a smoldering low-grade infection, may develop in some individuals. It may result in distention of the lacrimal sac, and massage may reflux mucoid material through the canalicular system onto the surface of the eye. If a tumor is not suspected, no further diagnostic evaluation is indicated to confirm the diagnosis of total NLDO. Chronic dacryocystitis is treated before elective intraocular surgery.

Neoplasm

Lacrimal Gland

Neoplasms of the lacrimal gland are discussed in Chapter 5.

Lacrimal Drainage System

Neoplastic causes of acquired obstruction of the lacrimal drainage system may be classified into the following groups:

- primary lacrimal drainage system tumors (most commonly papilloma and squamous cell carcinoma; Fig 15-26)
- primary tumors of tissues surrounding the lacrimal drainage system that secondarily invade or compromise lacrimal system structures (most commonly basal and squamous cell carcinoma of the eyelid skin; others include adenoid cystic carcinoma, infantile [capillary] hemangioma, inverted papilloma, epidermoid carcinoma, osteoma, and lymphoma)
- tumors metastatic to the nasolacrimal region

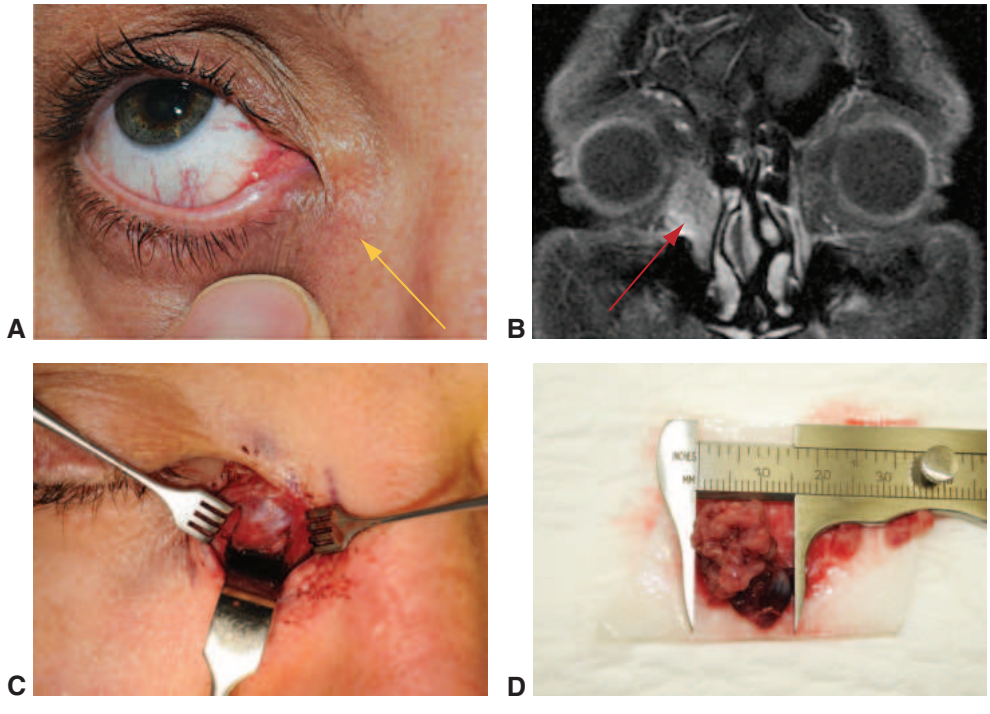

Figure 15-26 Papillary squamous cell carcinoma of the right lacrimal sac. **A,** Palpable mass over the right lacrimal sac *(arrow)*. **B,** Magnetic resonance imaging scan shows a mass within the right lacrimal sac *(arrow)*. **C,** Incisional biopsy through an external approach. **D,** Lacrimal sac biopsy reveals papillary squamous cell carcinoma. *(Courtesy of Bobby S. Korn, MD, PhD.)*

Primary lacrimal sac tumors are rare and should be considered for any mass that presents above the medial canthal tendon. They may be associated with epiphora or chronic dacryocystitis. Some patients report spontaneous bleeding; blood may also reflux from the punctum on irrigation (see Fig 15-10). Tumors that invade the skin may produce ulceration with telangiectasia over the lacrimal sac. Metastasis to regional lymph nodes may also occur. CT and MRI have replaced dacryocystography as the way to identify neoplasms and determine disease extent. CT also has the advantage of facilitating the assessment of bone erosion.

On histologic examination, approximately 45% of lacrimal sac tumors are benign and 55% are malignant. Squamous cell papillomas and carcinomas are the most common tumors of the sac. Many papillomas initially grow in an inverted pattern and into the lacrimal sac wall; consequently, their excision is often incomplete. With recurrence, malignant degeneration may occur.

Treatment of benign lacrimal sac tumors commonly requires a *dacryocystectomy* (surgical extirpation of the lacrimal sac). Malignant tumors require a dacryocystectomy combined with a lateral rhinotomy and medial maxillectomy, which are often performed in concert with a head and neck surgeon. *Exenteration,* including bone removal in the medial canthal area, is necessary if a malignant epithelial tumor involves bone and the soft tissues of the orbit (see Chapter 8). *Radiation* is useful for treatment of lymphomatous lesions, as an adjuvant after removal of malignant lesions, and as a palliative measure for unresectable lesions.

Additional Materials and Resources

Related Academy Materials

The American Academy of Ophthalmology is dedicated to providing a wealth of high-quality clinical education resources for ophthalmologists.

Print Publications and Electronic Products

For a complete listing of Academy clinical education products, including the BCSC Self-Assessment Program, visit our online store at aao.org/store. Or call Customer Service at 866.561.8558 (toll free, US only) or +1 415.561.8540, Monday through Friday, between 8:00 AM and 5:00 PM (PST).

Online Resources

Visit the **Ophthalmic News and Education (ONE®) Network** at aao.org/oculoplastics-orbit to find relevant videos, podcasts, webinars, online courses, journal articles, practice guidelines, self-assessment quizzes, images, and more. The ONE Network is a free Academy-member benefit.

The **Residents page** on the ONE Network (aao.org/residents) offers resident-specific content, including courses, videos, flashcards, and OKAP and Board Exam study tools.

The **Resident Knowledge Exchange** (resident-exchange.aao.org) provides peer-generated study materials, including flash cards, mnemonics, and presentations that offer unique perspectives on complex concepts.

Find comprehensive **resources for diversity, equity, inclusion, and accessibility** in ophthalmology on the ONE Network at aao.org/diversity-equity-and-inclusion.

Access free, trusted articles and content with the Academy's collaborative online encyclopedia, **EyeWiki,** at aao.org/eyewiki.

Get mobile access to *The Wills Eye Manual* and *EyeWiki,* watch the latest 1-minute videos, challenge yourself with weekly Diagnose This activities, and set up alerts for clinical updates relevant to you with the free **AAO Ophthalmic Education App.** Download today: search for "AAO Ophthalmic Education" in the Apple app store or in Google Play.

Requesting Continuing Medical Education Credit

The American Academy of Ophthalmology is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians.

The American Academy of Ophthalmology designates this enduring material for a maximum of 10 *AMA PRA Category 1 Credits*™. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

To claim *AMA PRA Category 1 Credits*™ upon completion of this activity, learners must demonstrate appropriate knowledge and participation in the activity by taking the posttest for Section 7 and achieving a score of 80% or higher.

To take the posttest and request CME credit online:

1. Go to aao.org/education/cme-central and log in.
2. Click on "Claim CME Credit and View My CME Transcript" and then "Report AAO Credits."
3. Select the appropriate media type and then the Academy activity. You will be directed to the posttest.
4. Once you have passed the test with a score of 80% or higher, you will be directed to your transcript. *If you are not an Academy member, you will be able to print out a certificate of participation once you have passed the test.*

CME expiration date: June 1, 2026. *AMA PRA Category 1 Credits*™ may be claimed only once between June 1, 2023 (original release date), and the expiration date.

For assistance, contact the Academy's Customer Service department at 866.561.8558 (US only) or +1 415.561.8540 between 8:00 AM and 5:00 PM (PST), Monday through Friday, or send an e-mail to customer_service@aao.org.

Study Questions

Please note that these questions are not part of your CME reporting process. They are provided here for your own educational use and for identification of any professional practice gaps. The required CME posttest is available online (see "Requesting Continuing Medical Education Credit"). Following the questions are answers with discussions. Although a concerted effort has been made to avoid ambiguity and redundancy in these questions, the authors recognize that differences of opinion may occur regarding the "best" answer. The discussions are provided to demonstrate the rationale used to derive the answer. They may also be helpful in confirming that your approach to the problem was correct or, if necessary, in fixing the principle in your memory. The Section 7 faculty thanks the Resident Self-Assessment Committee for developing these self-assessment questions and the discussions that follow.

1. The lateral canthal tendon attaches to what structure?
   a. lateral orbital rim
   b. lateral orbital tubercle
   c. orbicularis muscle
   d. Whitnall ligament

2. What sensory nerve enters the orbit through the superior orbital fissure?
   a. optic nerve
   b. maxillary division of cranial nerve V
   c. facial nerve
   d. ophthalmic division of cranial nerve V

3. What is the most common ocular finding in an infant with a unilateral small orbit and no visible eye?
   a. microphthalmia
   b. anophthalmia
   c. eyelid coloboma
   d. blepharophimosis

4. Failure of what embryonal developmental process results in microphthalmia with orbital cyst?
   a. neural crest cell migration
   b. choroidal fissure closure
   c. primary optic vesicle growth
   d. secondary optic vesicle degeneration

5. A 58-year-old man with poorly controlled diabetes mellitus presents to the emergency department with severe orbital pain, decreased vision, and proptosis. A computed tomography (CT) scan shows fulminant sinusitis with orbital invasion. A biopsy is performed, and Grocott-Gomori methenamine silver stain (GMS) shows septate branching hyphae of uniform width. What is the most likely diagnosis?
   a. mucormycosis
   b. echinococcosis
   c. aspergillosis
   d. cysticercosis

6. A 48-year-old woman has a well-circumscribed, intraconal, midorbital mass with progressive vision loss. Magnetic resonance imaging (MRI) reveals heterogenous gadolinium enhancement consistent with a cavernous venous malformation. What is the next step in managing this patient?
   a. observation
   b. cerebral arteriography
   c. gamma knife radio surgery
   d. surgical excision

7. A 45-year-old woman presents with axial proptosis and vision loss. On examination, her affected eye also has optic atrophy and an optociliary shunt vessel. Her MRI scan reveals enhancement of the optic nerve sheath around a darker, normal optic nerve. What is the most likely diagnosis?
   a. thyroid eye disease (TED)
   b. optic nerve sheath meningioma
   c. optic nerve glioma
   d. sphenoid wing meningioma

8. Pulsatile proptosis is most closely associated with what neuro-oculocutaneous disorder?
   a. tuberous sclerosis
   b. Von Hippel-Lindau Disease
   c. neurofibromatosis type 1(NF1)
   d. neurofibromatosis type 2 (NF2)

9. Why are orbital roof fractures more likely to occur in young children than in adults?
   a. There is better pneumatization of frontal sinuses in young children.
   b. There is overprojection of the midface in young children.
   c. There is a larger cranial vault-to-midface ratio in young children.
   d. The frontal lobe is underdeveloped in young children.

10. A patient arrives in the trauma bay after a motor vehicle crash in which he hit his face on the dashboard. He has ecchymosis and significant swelling to his right eye. The eyelids are "rock hard" to the touch. His visual acuity is 20/200 OD and 20/20 OS. He has a right afferent pupillary defect and limited extraocular movements of the right eye. IOP is 45 OD and 22 OS. What is the most appropriate next step?
    a. Perform an immediate lateral canthotomy and inferior cantholysis.
    b. Obtain CT of the orbits.
    c. Start maximum topical ocular antihypertensive eyedrops and recheck the pressure in 30 minutes.
    d. Perform orbital exploration in the operating room.

11. What is the best approach to an intraconal orbital tumor located between the optic nerve and the lateral rectus?
    a. retrocaruncular orbitotomy
    b. lateral orbitotomy
    c. medial orbitotomy
    d. vertical eyelid-splitting orbitotomy

12. Six months after enucleation, a patient returns to the office reporting mucoid discharge from the anophthalmic side. There is no pain. She states that the prosthesis fits well. What is the most likely cause of the mucus discharge?
    a. giant papillary conjunctivitis
    b. implant extrusion
    c. implant infection
    d. lower eyelid entropion

13. When one is operating in the region of the temporal fossa, in what tissue layer is the temporal (frontal) branch of cranial nerve VII found?
    a. deep temporal fascia
    b. temporoparietal fascia
    c. temporal fat pad
    d. subcutaneous tissue

14. What is the term for an extra row of eyelashes that emerge from the meibomian glands?
    a. trichiasis
    b. madarosis
    c. poliosis
    d. distichiasis

15. What is the genetic inheritance pattern for blepharophimosis?
    a. X-linked
    b. autosomal dominant
    c. autosomal recessive
    d. mitochondrial DNA

16. A patient with a history of "eyelid cancer" in the past now presents with ipsilateral forehead pain, diplopia, and ptosis. What condition is most likely responsible for these symptoms?
    a. Bowen disease
    b. squamous cell carcinoma
    c. basal cell carcinoma
    d. Muir-Torre Syndrome

17. What is the most common form of basal cell carcinoma (BCC)?
    a. morpheaform
    b. nodular
    c. multicentric
    d. basosquamous

18. A 33-year-old man arrives in the emergency department with blunt trauma to the right eyelid. He has a 1.5-cm horizontal laceration of the upper eyelid with prolapse of fat at the site of injury. What is the most important structure to evaluate prior to repair of the eyelid laceration?
    a. tarsal conjunctiva
    b. extraocular muscles
    c. globe
    d. levator aponeurosis

19. Why is a Hughes tarsoconjunctival flap contraindicated in young children?
    a. immature marginal arcade
    b. risk of amblyopia
    c. inadequate conjunctiva
    d. flaccidity of the tarsal plate

20. During patient evaluation, the ophthalmologist attempts to digitally elevate the margin of the lower eyelid to the superior corneal limbus with the eye in primary position. The inability to perform this maneuver suggests what diagnosis?
    a. spastic ectropion
    b. involutional entropion
    c. involutional ectropion
    d. cicatricial ectropion

21. What procedure that is used to correct punctal ectropion involves a horizontal fusiform excision of conjunctiva and eyelid retractors 4 mm inferior to the puncta?
    a. lateral tarsal strip
    b. punctoplasty
    c. medial spindle
    d. rotational suture repair

22. Lower eyelid retractor repair (reattachment) is most appropriate for correction of what condition?
    a. entropion without significant horizontal laxity
    b. lower eyelid retraction
    c. cicatricial entropion
    d. mechanical ectropion

23. A patient has eyelid malposition. The ophthalmologist recommends mucosal grafting with additional surgical repair. What eyelid malposition is most likely to lead to this recommendation?
    a. cicatricial ectropion
    b. cicatricial entropion
    c. spastic entropion
    d. involutional ectropion

24. In a patient with asymmetric ptosis, how is ptosis unmasked in the contralateral eye?
    a. careful measurement of the margin–reflex distance (MRD)
    b. instillation of phenylephrine 2.5%
    c. lifting of the more ptotic eyelid
    d. ice-pack test

25. Middle lamellar deficiency most commonly results from surgical or traumatic shortening of what structure?
    a. orbicularis muscle
    b. orbital septum
    c. conjunctival and eyelid retractors
    d. tarsal plate

26. When an endoscopic brow lift is performed, the incision in each temporal region can result in what complication?
    a. damage to cranial nerve (CN) VII
    b. damage to CN V
    c. eyelid ptosis
    d. Horner syndrome

27. Darkly pigmented skin increases the risk of what complication of laser skin resurfacing?
    a. lagophthalmos
    b. postoperative inflammatory hyperpigmentation
    c. lower eyelid retraction
    d. herpes simplex virus outbreak

28. What bone forms the anterior portion of the nasolacrimal fossa?
    a. ethmoid bone
    b. lacrimal bone
    c. maxillary bone
    d. palatine bone

29. The lacrimal pump system is driven by what nerve?
    a. CN III
    b. CN V
    c. CN VII
    d. lacrimal nerve

30. A 2-year-old child is brought into the clinic because the mother notes tears constantly running down the child's face. There is no reflux on palpation of the lacrimal sac and there is no increased tear film height. There is a small tuft of eyelashes a few millimeters lateral to and above the eyelash line. What is the proper management?
    a. probing of the puncta and canaliculi
    b. probing and intubation of the lacrimal system
    c. excision of aberrant ductules
    d. observation

Answers

1. **b.** The lateral canthal tendon attaches at the lateral orbital tubercle, also known as the Whitnall tubercle. The Whitnall ligament is a separate fascial band that does not insert on the tubercle of the same name. The lateral orbital tubercle is posterior to the orbicularis oculi muscle and lateral orbital rim.
2. **d.** The ophthalmic division of cranial nerve V enters the orbit through the superior orbital fissure. The optic nerve enters through the optic canal, and the maxillary division of cranial nerve V enters through the foramen rotundum. The facial nerve is a motor nerve and does not enter the orbit.
3. **a.** Microphthalmia is defined by the presence of a small eye with an axial length that is at least 2 standard deviations below the mean axial length for age. Microphthalmia is much more common than anophthalmia, and the vast majority of microphthalmic eyes have no potential for vision. Although no visible eye may be present, most of these patients actually have a microphthalmic globe. The defect can be isolated or occur with a constellation of abnormalities as part of a syndrome. An eyelid coloboma is a characterized by a congenital defect of the eyelid margin, and blepharophimosis is characterized by eyelid malpositions in the presence of a normal orbit.
4. **b.** Microphthalmia with orbital cyst results from failure of the choroidal fissure to close in the embryo. Craniofacial clefts occur as a result of a developmental arrest or mechanical disruption of development. Etiologic theories include a failure of neural crest cell migration and a failure of fusion or movement of facial processes. Anophthalmia occurs when the primary optic vesicle fails to grow out from the cerebral vesicle at the 2-mm stage of embryonic development. Consecutive anophthalmia is thought to result from a secondary degeneration of the optic vesicle.
5. **c.** The clinical scenario described is a classic presentation of acute invasive aspergillosis. On Grocott-Gomori methenamine silver (GMS) stain, *Aspergillus* is characterized by branching, septate hyphae. Mucormycosis also would be on the differential diagnosis of acute sino-orbital disease in a patient with poorly controlled diabetes. However, GMS stain demonstrates broad, nonseptate hyphae in mucormycosis. Echinococcosis is caused by a dog tapeworm; it can sometimes cause progressive inflammation and a severe immune response if there is rupture of an orbital cyst. It is not associated with sinus disease. Cysticercosis is caused by the *Taenia solium* parasite and may rarely cause orbital infection. The enzyme-linked immunosorbent assay (ELISA) for serum antibodies may aid in diagnosis.
6. **d.** Cavernous venous malformations (CVMs; previously known as cavernous hemangiomas) are common orbital lesions of young to middle-aged adults, with a female predilection. On magnetic resonance imaging (MRI), a characteristic heterogeneous enhancement pattern is often seen during initial gadolinium infusion that becomes homogeneous as the study progresses; this feature greatly narrows the differential diagnosis. In atypical cases, specific MRI and magnetic resonance angiography (MRA) sequences may be very helpful in differentiating these lesions from active venolymphatic or arteriovenous malformations, usually abrogating the need for and inherent risks of cerebral arteriography. Computed tomography has less-specific patterns: longstanding lesions may exhibit areas of calcification. Although cavernous venous malformations usually grow slowly, the presence of a

compressive optic neuropathy typically requires intervention. Although some patients with early optic neuropathy may opt for observation to at least temporarily avoid the risks of treatment, surgical intervention should be offered. While stereotactic radiotherapy, including gamma knife radiosurgery, may be an option for lesions that are difficult to access in the orbital apex, anterior or mid-orbital lesions typically do well with excisional surgery. Observation with serial examinations and imaging is certainly a reasonable option if the CVM is found incidentally and the patient is asymptomatic.

7. **b.** Optic nerve meningiomas arise in the arachnoid of the optic nerve sheath and enlarge to cause compression of the optic nerve. They occur most commonly in women in the third and fourth decades of life. Pertinent clinical features include gradual, painless, unilateral loss of vision. There can be axial proptosis and the nerve can appear normal, swollen, or atrophic. Optociliary shunt vessels may be present. Optic nerve sheath meningiomas may be associated with neurofibromatosis type 2, especially if bilateral. Enhancement of the lesion surrounding the optic nerve results in the "tram-track" sign on axial imaging or a doughnut appearance on coronal sections. Optic nerve gliomas usually show fusiform enlargement of the optic nerve. Thyroid eye disease (TED) does not usually present as described. Sphenoid wing meningiomas arise from the meninges and originate intracranially and extend into the orbit. Imaging may show hyperostosis and calcifications, along with dural enhancement on MRI.
8. **c.** Orbital pulsations can occur in various situations and can often be divided, depending on the presence or absence of a bruit. With bruits, pulsations can be seen in carotid cavernous fistulas, orbital arteriovenous fistulas, and dural arteriovenous fistulas. Without bruits, they can be found in meningoencephaloceles, neurofibromatosis 1 (NF1), and in cases involving orbital roof defects, such as removal of the orbital roof. Sphenoid wing dysplasia or aplasia in NF1 is associated with this orbital finding. Patients with NF1 with pulsatile proptosis have sphenoid wing dysplasia or aplasia. Tuberous sclerosis, von Hippel-Lindau disease, and neurofibromatosis type 2 (NF2) are other neuro-oculocutaneous disorders (phakomatoses) but are not associated with pulsatile exophthalmos.
9. **c.** Orbital roof fractures occur much more commonly in young children than adults for 2 main reasons. First, pneumatized frontal sinuses, the structures that absorb much of the force of a frontal blow in adults, are not yet developed in children. This absence of pneumatized frontal sinuses allows force to be transferred directly to the orbital roof, resulting in fracture. Second, an infant or toddler has a much higher cranial vault-to-face ratio than an adult (8:1 vs 2:1, respectively) along with a flatter face, lacking the midfacial and nasal projection of adults. This results in a larger and more prominent forehead that is more susceptible to injury. The frontal lobe is not underdeveloped in young children.
10. **a.** To preserve visual function, immediate canthotomy and cantholysis should be performed to decompress the orbit. Orbital compartment syndrome is caused by hemorrhage in the orbit, leading to optic nerve compression and compromised arterial perfusion. This patient is experiencing increased intraocular pressure as well as decreased visual acuity and color vision, which suggests optic nerve involvement. The most appropriate next step is to intervene with a canthotomy and cantholysis. The other options would only delay emergency treatment.
11. **b.** An intraconal tumor located between the lateral rectus muscle and the optic nerve is best approached with a lateral orbitotomy, with or without a bone flap. Vertical eyelid-

splitting orbitotomy is best for superior lesions, while retrocaruncular and medial orbitotomy are best for lesions in the medial orbit.

12. **a.** Chronic mucus discharge from an anophthalmic socket is usually due to giant papillary conjunctivitis. This is due to mechanical friction between the palpebral conjunctival surface and the prosthesis. Everting the upper eyelid will demonstrate the papillary reaction. Treatment consists of topical corticosteroids, mast cell stabilizers, and, occasionally, prosthetic modification. Implant extrusion can present in a similar fashion, but it is less common than papillary conjunctivitis. Implant infection is usually painful, and examination reveals purulent discharge. The weight of the prosthesis can stretch the lower eyelid over time, but this typically manifests as lower eyelid laxity with or without ectropion rather than entropion.
13. **b.** In the temporal area, the temporal (frontal) branch of cranial nerve VII crosses the zygomatic arch and courses superomedially in the deep layers of the temporoparietal fascia (also called the superficial temporalis fascia), often near branches of the temporal artery. The facial nerve branches inferior to the zygomatic arch are deep to the superficial musculoaponeurotic system (SMAS). The temporal branch of the facial nerve is found within the superficial portion of the temporoparietal fascia (an extension of the SMAS).
14. **d.** Distichiasis, which can be acquired or congenital, is defined as accessory eyelashes growing posterior to the normal row of eyelashes (from the meibomian glands or tarsus). Trichiasis is defined as an acquired misdirection of eyelashes that curve toward the ocular surface. Madarosis is the absence or loss of the eyelashes. Poliosis refers to a decrease or absence of melanin in the eyelashes.
15. **b.** Blepharophimosis (also called blepharophimosis-ptosis-epicanthus inversus syndrome [BPES] or blepharophimosis syndrome) is usually inherited in an autosomal dominant fashion. Myogenic congenital ptosis, which is a condition in the differential diagnosis, is transmitted in an autosomal recessive manner. Additionally, Turner syndrome is associated with ptosis and complete absence of 1 X chromosome or structural changes in the chromosome. Chronic progressive external ophthalmoplegia is typically associated with mitochondrial transmission.
16. **b.** This patient presents with a classic "cavernous sinus syndrome"—facial sensory changes (in this case limited to the first division of the trigeminal nerve), diplopia, and ptosis. A history of cutaneous squamous cell carcinoma (SCCA) of the upper eyelid should immediately raise the strong probability that perineural spread of the tumor has occurred along the skull base. Cutaneous SCCA carcinoma has a propensity for spread along sensory nerves (and on occasion along the facial nerve). It is notorious for recurrence in this cryptic fashion, even with "clear margins" on initial extirpation. The sensory changes may precede other cranial neuropathy by weeks to months, and the symptoms are often misdiagnosed as a "pain syndrome" or trigeminal neuralgia. The affected sensory nerve is usually enlarged and enhanced on MRI, but these findings may be subtle and missed by the radiologist without a good clinical history. In many cases, no previous history of cutaneous SCCA is present, but the patient either has widespread actinic changes over the face (with an undiagnosed SCCA) or has undergone multiple sessions of cryotherapy or cautery of suspicious facial lesions without biopsy. Bowen disease is another name for squamous cell carcinoma in situ of the skin. In situ carcinomas are not metastatic and would not cause these symptoms. Basal cell carcinoma does not spread by perineural invasion. Muir-Torre

syndrome is an autosomal dominant condition of sebaceous tumors involving the gastrointestinal, endometrial, or urologic systems.

17. **b.** Nodular BCC is the most common form of basal cell carcinoma. It presents as a firm, raised, pearly nodule that may have telangiectasias and central ulceration. Morpheaform is less common and behaves more aggressively than the nodular form. Multicentric, or superficial, BCC can silently spread across the eyelid margin and mimic blepharitis. Basosquamous is a rare, aggressive variant with features of BCC and squamous cell carcinoma. BCC lesions are most often located on the lower eyelid and are typically painless. Conjunctival extension can occur, but it is not a typical feature of basal cell carcinoma.

18. **c.** In any periocular injury, a detailed examination of the globe to rule out rupture or other serious intraocular injury is of paramount importance. With an isolated, penetrating periocular injury, the only reason to delay a dilated intraocular examination is the presence of neurologic symptoms suggestive of acute intracranial injury. Although a detailed examination of the inner aspect of the eyelids (eg, the tarsal conjunctiva) is necessary, it can wait until the globe is "cleared." Penetrating injury with visible periocular fat raises the possibilities of even deeper injury to the skull base, including penetrating intracranial injury and occult orbital or intracranial foreign body, despite the history of "blunt trauma." CT imaging of the orbit and brain are indicated in such cases.

19. **b.** A standard Hughes flap requires 2 to 4 weeks of occlusion and therefore creates a risk of amblyopia. The marginal arcades are adequately developed in children. The tarsal plate has adequate rigidity in children and there is no shortage of conjunctiva.

20. **d.** In cicatricial ectropion, there is a vertical shortage of the anterior lamella, preventing manual repositioning of the eyelid. Potential causes include thermal or chemical burns, mechanical or surgical trauma (tumor removal or blepharoplasty), chronic actinic sun damage, rosacea, atopic dermatitis, eczematous dermatitis, herpes zoster, and ichthyosis. In spastic and involutional entropion and involutional ectropion, one can return the eyelid to a normal position using digital traction.

21. **c.** In cases of mild medial ectropion with punctal eversion, a medial spindle procedure can be performed. The procedure involves a horizontal fusiform excision of conjunctiva and eyelid retractors 4 mm inferior to the puncta, followed by inverting sutures for closure. In cases with associated horizontal eyelid laxity, lateral canthal tightening may be used in conjunction with this procedure. In the lateral tarsal strip procedure, the tarsus is sutured directly to the lateral orbital rim periosteum. The goal of this procedure is to correct the position of the eyelid while maintaining the horizontal dimension of the palpebral fissure and a sharp, correctly positioned lateral canthal angle. Punctoplasty changes the size of the puncta and does not alter the punctal position relative to the globe. Rotational suture techniques are used as temporizing measures for involutional entropion; however, when these techniques are used in isolation, recurrence is anticipated.

22. **a.** The lower eyelid retractor muscles include the capsulopalpebral fascia and the inferior tarsal muscle. Reinsertion of the lower eyelid retractors is performed to repair involutional entropion. In addition to reinsertion of the lower eyelid retractors, partial myectomy of the preseptal orbicularis oculi muscle can be performed, as can tightening of the lower eyelid with a lateral tarsal strip procedure. These procedures address the 3 principal mechanisms behind involutional entropion: 1) horizontal laxity of the eyelid, 2) disinsertion or atrophy of the lower eyelid retractor complex, and 3) an overriding preseptal orbicularis oculi muscle. In contrast, cicatricial entropion repair requires addressing the

underlying problem (eg, controlling inflammation, autoimmune reaction, infection, or trauma) and using a graft to lengthen the posterior lamella. Mechanical ectropion is characterized by an eyelid mass that causes external rotation of the eyelid margin.

23. **b.** In cases of cicatricial entropion, the shortened posterior lamella must be augmented to correct the eyelid malposition. This requires a mucosal graft such as hard palate. In contrast, cicatricial ectropion with anterior lamella deficiency requires a skin graft. Spastic entropion does not require tissue augmentation. Involutional ectropion would worsen with a posterior lamellar mucosal graft.

24. **c.** In a patient with asymmetric ptosis, lifting the more affected eyelid may unmask ptosis in the contralateral eye. This is because of Hering's law of equal innervation. Measurement of the margin–reflex distance (MRD) helps to document the amount of ptosis and plan for repair but does not unmask a hidden ptosis. Phenylephrine can be used to determine who is a candidate for an internal approach to ptosis repair (Muller muscle resection). An ice-pack test can be used to evaluate suspected cases of myasthenia gravis.

25. **b.** Middle lamellar deficiency results from shortening of the orbital septum and surrounding tissues and is generally caused by trauma or surgery. The clinical findings associated with middle lamella injury include eyelid retraction in the presence of normal amounts of skin and conjunctiva, inferior keratoconjunctivitis, and an eyelid that is usually stiff or tethered to the rim. Middle lamellar deficiency can also be associated with anterior and posterior lamellar eyelid scarring. Surgical correction usually requires lysis of cicatrix (including septal scarring) and possible placement of a spacer graft.

26. **a.** The temporal pocket is created in the plane of the deep temporalis fascia. Dissection in this plane spares the frontal branch of the facial nerve in the overlying superficial temporalis fascia. However, if the dissection is carried out in the incorrect plane, damage to CN VII can occur. Additionally, during the temporal dissection, the temporal artery can also be encountered, which can result in hemorrhage and/or hematoma. Another complication of the scalp incisions is alopecia. Eyelid ptosis would result from a CN III injury, which is not encountered during an endoscopic brow lift. Dissection leading to the periosteal release at the medial aspect of the orbital rim can lead to CN V damage. Horner syndrome would result from damage to the sympathetic nerve chain, which is not encountered during this procedure.

27. **b.** In the 1990s, an ultrapulsed carbon dioxide (CO_2) laser was developed that allowed skin resurfacing without the adverse effect of thermal-induced skin damage and scarring. Pauses between the pulses of the laser allow cooling of the tissue to minimize thermal damage. The CO_2 laser can shrink skin and tighten collagen and is useful as an adjunct to blepharoplasty. Complications include eyelid retraction, exposure keratopathy, lagophthalmos, and ectropion. The CO_2 laser is contraindicated in patients who have taken isotretinoin (Accutane) within the past 12 months, because skin healing is delayed. In addition, the CO_2 laser is contraindicated in patients with active collagen vascular disorders, such as lupus. Caution must be used in patients with darker skin pigmentation, due to the risk of postoperative inflammatory hyperpigmentation. If patients have a history of herpes simplex, they are often treated preoperatively with oral antiviral medications to prevent an outbreak postoperatively that may result in scarring.

28. **c.** The medial wall of the orbit is composed of 4 bones from anterior to posterior: maxilla, lacrimal, ethmoid, and the body and lesser wing of the sphenoid bone. The lacrimal sac fossa is bounded anteriorly by the ascending process of the maxilla, which forms the

anterior lacrimal crest. The maxillary bone fuses with the lacrimal bone within the fossa, and the lacrimal bone goes on to form the posterior lacrimal crest. A small portion of the palatine bone juts up in the posterior orbit to form a portion of the orbital floor.

29. **c.** The lacrimal pump is driven by the action of the pretarsal orbicular oculi muscle, which is innervated by the facial nerve, or CN VII. Blinking pushes the tears from the lateral eyelid margin to the nasal eyelid margin. When the eyelids open, negative pressure pulls the tears into the sac; when the eyelids close, the action of the orbicularis muscle creates positive pressure that forces those tears through the nasolacrimal duct. CN III is the oculomotor nerve that supplies the medial, superior, and inferior rectus and oblique muscles, as well as the levator muscle. CN V is the trigeminal nerve; it supplies sensory innervation to the face as well as motor innervation to some muscles of mastication. The lacrimal nerve carries parasympathetic innervation to the lacrimal gland as part of the lacrimal secretory system.

30. **c.** When present, aberrant lacrimal ductules are found several millimeters lateral and superior to the eyelash line. These ductules can lead to tearing on the skin, which mimics epiphora. Accessory lacrimal ductules are usually accompanied by a tuft of eyelashes. Simple excision is the treatment. The absence of discharge or increased tear film suggest that this symptom is not a result of an obstruction of the lacrimal system, a condition that could improve with either probing or probing and intubation of the lacrimal system. Observation would not resolve the tearing.
